

### Structured abstract (249/250 words)

**Background:** Suicide rates between 1999 and 2016 have been on the rise in the United States (U.S.). Examining state-level trends in, and contributing circumstances to, suicide, can inform movement towards the goal of comprehensive state suicide prevention.

**Methods:** Trends in age-adjusted suicide rates, overall and by sex and state, among people aged  $\geq 10$ , were calculated using data from the National Vital Statistics System. Changes in rates and state rankings were assessed across six consecutive three-year periods (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013, 2014-2016). Data from the 2015 National Violent Death Reporting System, across 27 states, were analyzed to compare circumstances between suicide decedents with and without known mental health problems.

**Results:** Average annual percentage change in suicide rates across the period, increased significantly in the U.S. overall (25.4%) and in 44 states, ranging from 5.9% in Delaware to 57.6% in North Dakota. People with (46%) and without (54%) known mental health problems, experienced a range of multiple contributing circumstances to their suicides, including substance use, relationship problems, and recent crises.

**Conclusions:** Suicide rates have risen significantly in the U.S. and across most states from 1999-2016. Numerous factors contribute to suicide among people with and without known mental health problems.

**Implications for Public Health Practice:** To reverse upward trends in suicide, a population-based public health approach inclusive of evidence-based strategies across multiple levels (individual, family/relationship, community, societal), focused on preventing risk before it starts, identifying and supporting people already at risk, preventing-re-attempts, and caring for survivors after a suicide, is needed.

### INTRODUCTION ((263/250 words)

In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> While overall rates have been on the decline globally,<sup>2</sup> rates of suicide in the U.S. have increased between 1999 and 2016 across most age groups, among males and females, across racial/ethnic groups, and across urbanization levels.<sup>3</sup> Rates of nonfatal attempts have also been on the rise, with emergency department visits for self-harm injury having increased more than 40% between 2001 and 2015.<sup>5</sup> In 2015, the economic toll of suicides and self-harm injuries totaled more than \$69 billion in direct medical and work loss costs. Suicide is rarely caused by one thing; rather, the risk factors for suicide are numerous and occur at multiple levels (individual, family/relationship, community, and societal).<sup>6</sup> However, the focus tends to point towards mental illnesses, such as depression and bipolar disorder, as the cause. Other factors associated with suicide include lack of social connectedness, downturns in the economy, access to lethal means (e.g. substances, firearms) among people at risk, lack of access to quality evidence-based treatment, irresponsible media reporting, lack of coping/problem-solving skills, stigma associated with help-seeking, and a prior suicide attempt, among others. While the Surgeon General called for a comprehensive public health approach to suicide prevention in 1999, to date, the U.S. continues to struggle to make this a reality due to a lack of funding for implementation of evidence-based prevention strategies, misperceptions about suicide preventability, and a prevention focus primarily downstream, at the individual level.

**Comment [SD()]:** Does this seem too abrupt or unclear as in, "why look at suicide within those two groups?"

**Comment [SD()]:** Could also say, no single factor alone contributes to suicide.

**Comment [SD()]:** If NCHS data brief has urbanization we can take this reference out if we need space for others.

**Comment [SD()]:** This needs updating for 2016 but ED data is still for 2015.

**Comment [SD()]:** Need idea for reference here.

**Comment [SD()]:** Do we want to say opioids as an example here instead so that we can tie this in??

<sup>5</sup> WISQARS Nonfatal injury reports

<sup>6</sup> National Strategy for Suicide Prevention

## METHODS (179/250 words)

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03). Age-specific population estimates were obtained from U.S. Census Bureau / National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods covering years 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from the 2015 National Violent Death Reporting System (NVDRS), from 27 states, were used to compare the characteristics, including precipitating circumstances, of suicide decedents with and without known mental health problems. NVDRS compiles data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports.

## RESULTS (166/600 words)

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally. Geographically, many states showing the largest percentage increases are in the upper Great Plains and the upper Intermountain West (Map).

Modeled suicide rates trends were found to be significantly increasing for 44 states, as well as for the U.S. overall (Table 1). By sex, rate trends were found to be significantly increasing in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

INSERT KATIE'S RESULTS HERE

## DISCUSSION (920/700 words)

The current study highlights state-specific trends in suicide among people  $\geq 10$  years, over time by state and by sex. It also provides a snapshot of circumstances of suicide among people with and without known mental health problems to provide insight into the growing suicide problem in the US. Findings that national suicide rates increased significantly, overall (+25.4%), and among both males and females, aligns with past studies reporting on rate increases over time and across demographic subgroups.<sup>3,4,7</sup> To extend this information, novel state-specific trend analyses identified overall suicide rate increases in 44 states. Five remaining states and D.C. reported non-significant rate increases and Nevada, showed an overall decline in suicide rates.

The geographic distribution of rate increases suggests that many regions already known to have the highest rates of suicide in the country (e.g. mountain west), also experienced some of the largest percent increases in suicide rates. Conversely, regions that once seemed more protected from suicide (e.g. northeast, midwest) also saw large percent rate increases. Explanations for these increases may relate, in part, to the opioid overdose

**Comment [SD():** We need to consider changing this as I don't have space to include in the abstract, intro, and it hasn't been included in the methods—basically not incorporated at all.

**Comment [SD():** We also have some additional data that is forthcoming on the types of recent crises, FYI so that may be added as well.

**Comment [SD():** Thinking to put something in here about the overlap in suicide rates and opioid overdose deaths.

<sup>7</sup> Asha's paper

epidemic that occurred over the same time period,<sup>8</sup> and the downturn in the economy in the period 2007-2009.<sup>9</sup>

Some studies also suggest a negative impact of social media, particularly among youth.<sup>10</sup>

Related to gender, female suicide rates increased in more states (43) than did male suicide rates (34). This may hint at a narrowing of the suicide gender gap, as has been found related to suicide in other demographic groupings (e.g. by urbanization level).<sup>4,7</sup> It also aligns with reports of large increase in middle aged female suicides between 1999-2014.<sup>11</sup> This may signal an increases in risk factors more common among females (e.g., intimate partner violence) or may reflect a differential impact of common suicide risk factors (e.g., substance abuse) by sex. More research on this topic is needed.

Mental illness is an import risk factor for suicide. Unlike other studies,<sup>12</sup> the current study found that more than half of people (54%) did *not* have a known mental health problem. Among people who did, just over half were known to be in treatment at the time of their deaths, about one-third were reported to never have received any mental health treatment, and between about 30-40% had a history of ideation and/or suicide attempts. This points to the need for increased identification of, and improved responses to, people at risk, and highlights the need for better access to care that is evidence-based (e.g. collaborative), affordable, and sustained in order to prevent suicide attempts, re-attempts, and suicide.

While there is a tendency to focus primary attention to the risk fact of mental illness, risk factors for suicide are manifold. Stratifying analyses by suicides among people with and without known mental health problems allowed for the examination of other contributing risk factors within these groups. Results suggest many differences in the prevalence of circumstances, for example people without mental health problems were more likely to have criminal-legal problems, eviction/loss of home, and recent crises. However, some circumstances such as intimate partner problems, arguments/conflicts, recent crises, and physical health problems are common across groups. Whether the two groups are viewed as more similar or more unique, results are clear that multiple challenging life circumstances impacted both.

Both state trends and circumstance findings point to the same solution—the need for a comprehensive public health approach to suicide, inclusive of multiple and multi-level evidence-based strategies and approaches that: i) prevent suicide risk before it occurs, e.g., by strengthening economic supports, strengthening access to, and coverage of, care that is safe and effective; creating protective environments (e.g. reducing access to lethal means among people at risk); promoting connectedness, and teaching coping and problem-solving skills; ii) identify and support people already at risk, e.g. through gatekeeper training, crisis intervention, referral to effective treatments, and prevention of re-attempts; and iii) lessen harms after a suicide (e.g., supporting survivors and promoting responsible media reporting to avoid suicide contagion).<sup>13</sup> As of yet, no state has been able to implement such a comprehensive approach.

#### Limitations

The findings provided of this report are subject to at least two limitations. Data for state level analyses extend to 2016, the date for which the most recent mortality data is available, and data from NVDRS come from 2015 and cover only 27 states. Abstractors of NVDRS data are limited to data included in the investigative reports they

Comment [SD(): May take this out.

Comment [SD(): Is this too pointed or strong?

Comment [SD(): This is a slightly different way to present this info. What do you think?

Comment [SD(): Is it nationally representative at this point? Or no?

receive. For example, medical and mental health information are not captured directly from medical records but from coroner/medical examiner reports and the decedent's family members and friends. Therefore, the completeness and accuracy of this information are limited by the knowledge of the informant. This may explain some of the discrepancy between the prevalence of mental health disorders reported here (54%) and the 90% statistic frequently cited in other studies.<sup>14</sup>

## Conclusions

Suicide is a growing public health problem with states experiencing large increases in rates between 1999 and 2016. Mental illness is an important risk factor for suicide and it is one of many factors. Comprehensive suicide prevention strategies are needed in states that encompass risk factors at multiple levels and that work to prevent suicide risk before it occurs, to identify and successfully support people at-risk, and that lessens future harms.

<sup>6</sup> National Strategy for Suicide Prevention

current study examines increases in state suicide rates over time and circumstances contributing to suicide among people with and without mental health problems.

#### **METHODS (179/250 words)**

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03). Age-specific population estimates were obtained from U.S. Census Bureau / National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods covering years 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from the 2015 National Violent Death Reporting System (NVDRS), from 27 states, were used to compare the characteristics, including precipitating circumstances, of suicide decedents with and without known mental health problems. NVDRS compiles data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports.

#### **RESULTS (756/600 words)**

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally. Geographically, many states showing the largest percentage increases are in the upper Great Plains and the upper Intermountain West (Map).

Modeled suicide rates trends were found to be significantly increasing for 44 states, as well as for the U.S. overall (Table 1). By sex, rate trends were found to be significantly increasing in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known mental health (MH) problems were compared. Both groups were predominately male and predominately non-Hispanic white. Fifteen percent of those with known mental health problems and 20% without had ever served in the U.S. military.

Suicide decedents without known MH problems had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of race/ethnicity other than non-Hispanic white (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They had significantly greater odds of dying by suicide after committing homicide(s) (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3).

Although firearms were the most common injury mechanism for both groups, suicide decedents with known MH problems more often died by poisoning than those without MH problems (19.8% vs. 10.4%), most frequently due to overdose of over-the-counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

**Comment [SD]:** Need to decide on decedent or victims. Both are used here. I prefer decedent.

**Comment [SD]:** We need to consider changing this as I don't have space to include in the abstract, intro, and it hasn't been included in the methods—basically not incorporated at all.

All suicide decedents with known MH problems (N=9,407) and approximately 85% without known MH problems (N=9,357) had known precipitating circumstances. Decedents without known MH problems had significantly greater odds of any type of relationship problem or loss (aOR = 1.3, 95% CI = 1.2-1.4), intimate partner problems specifically (aOR = 1.4, 95% CI = 1.3-1.5), an argument or conflict (aOR = 1.4, 95% CI = 1.3-1.5), and having been a recent perpetrator of interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4) noted as a factor precipitating suicide. Decedents with known MH problems more frequently had a history of mental health or substance abuse treatment (67.2% vs. 4.2%), and co-occurring substance abuse problems (31.6% vs. 25%,  $p \leq .01$ ),

Suicide decedents without known MH problems had significantly greater odds of other life stressors as precipitating circumstances, including recent/impending criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9), and eviction/loss of home (aOR = 1.4, 95% CI 1.2-1.6). They had significantly lower odds of recent release from an institution of any kind, but when this was indicated, significantly greater odds of recent release from a correctional facility (aOR = 4.5, 95% CI = 3.2-6.3), or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Of those decedents with known MH problems who were recently released from an institution, 42.8% had been recently released from a psychiatric institution. Those with known MH problems also more frequently had job or financial problems (16.8% vs. 15.6%;  $p \leq .05$ ).

Decedents without known MH problems had significantly greater odds of a recent/impending crisis (aOR = 1.4, 95% CI = 1.3-1.5). When the type of crisis was known, it was most frequently a problem related to an intimate partner (36.2%), physical health (13.8%), criminal legal issues (13.6%), a family relationship (7.1%), or a job (5.3%). Over one-fourth of decedents with a known MH problem also had recent or impending crises, most frequently related to problems with an intimate partner (34.9%), physical health (12.9%), or a family relationship (8.7%). Decedents without known MH problems had significantly greater odds of criminal legal (aOR = 1.6, 95% CI = 1.3-1.9), and significantly lesser odds of job-related (aOR = 0.7, 95% CI = 0.5-0.8) crises.

Suicide decedents without known MH problems had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MH problems more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

## DISCUSSION (920/700 words)

The current study highlights state-specific trends in suicide among people  $\geq 10$  years, over time by state and by sex. It also provides a snapshot of circumstances of suicide among people with and without known mental health problems to provide insight into the growing suicide problem in the US. Findings that national suicide rates increased significantly, overall (+25.4%), and among both males and females, aligns with past studies reporting on rate increases over time and across demographic subgroups.<sup>3,4,7</sup> To extend this information, novel state-specific trend analyses identified overall suicide rate increases in 44 states. Five remaining states and D.C. reported non-significant rate increases and Nevada, showed an overall decline in suicide rates.

The geographic distribution of rate increases suggests that many regions already known to have the highest rates of suicide in the country (e.g. mountain west), also experienced some of the largest percent increases in suicide rates. Conversely, regions that once seemed more protected from suicide (e.g. northeast, midwest) also saw large percent rate increases. Explanations for these increases may relate, in part, to the opioid overdose epidemic that occurred over the same time period,<sup>8</sup> and the downturn in the economy in the period 2007-2009.<sup>9</sup> Some studies also suggest a negative impact of social media, particularly among youth.<sup>10</sup>

**Comment [SD()]:** We also have some additional data that is forthcoming on the types of recent crises, FYI so that may be added as well.

**Comment [SD()]:** Thinking to put something in here about the overlap in suicide rates and opioid overdose deaths.

**Comment [SD()]:** May take this out.

<sup>7</sup> Asha's paper

<sup>8</sup> <https://www.cdc.gov/mmwr/preview/mmwrhtml/mm6450a3.htm> Rudd et al MMWR 2016

Related to gender, female suicide rates increased in more states (43) than did male suicide rates (34). This may hint at a narrowing of the suicide gender gap, as has been found related to suicide in other demographic groupings (e.g. by urbanization level).<sup>4,7</sup> It also aligns with reports of large increase in middle aged female suicides between 1999-2014.<sup>11</sup> This may signal an increases in risk factors more common among females (e.g., intimate partner violence) or may reflect a differential impact of common suicide risk factors (e.g., substance abuse) by sex. More research on this topic is needed.

Mental illness is an import risk factor for suicide. Unlike other studies,<sup>12</sup> the current study found that more than half of people (54%) did *not* have a known mental health problem. Among people who did, just over half were known to be in treatment at the time of their deaths, about one-third were reported to never have received any mental health treatment, and between about 30-40% had a history of ideation and/or suicide attempts. This points to the need for increased identification of, and improved responses to, people at risk, and highlights the need for better access to care that is evidence-based (e.g. collaborative), affordable, and sustained in order to prevent suicide attempts, re-attempts, and suicide.

While there is a tendency to focus primary attention to the risk fact of mental illness, risk factors for suicide are manifold. Stratifying analyses by suicides among people with and without known mental health problems allowed for the examination of other contributing risk factors within these groups. Results suggest many differences in the prevalence of circumstances, for example people without mental health problems were more likely to have criminal-legal problems, eviction/loss of home, and recent crises. However, some circumstances such as intimate partner problems, arguments/conflicts, recent crises, and physical health problems are common across groups. Whether the two groups are viewed as more similar or more unique, results are clear that multiple challenging life circumstances impacted both.

Both state trends and circumstance findings point to the same solution—the need for a comprehensive public health approach to suicide, inclusive of multiple and multi-level evidence-based strategies and approaches that: i) prevent suicide risk before it occurs, e.g., by strengthening economic supports, strengthening access to, and coverage of, care that is safe and effective; creating protective environments (e.g. reducing access to lethal means among people at risk); promoting connectedness, and teaching coping and problem-solving skills; ii) identify and support people already at risk, e.g. through gatekeeper training, crisis intervention, referral to effective treatments, and prevention of re-attempts; and iii) lessen harms after a suicide (e.g., supporting survivors and promoting responsible media reporting to avoid suicide contagion).<sup>13</sup> As of yet, no state has been able to implement such a comprehensive approach.

#### Limitations

The findings provided of this report are subject to at least two limitations. Data for state level analyses extend to 2016, the date for which the most recent mortality data is available, and data from NVDRS come from 2015 and cover only 27 states. Abstractors of NVDRS data are limited to data included in the investigative reports they receive. For example, medical and mental health information are not captured directly from medical records but from coroner/medical examiner reports and the decedent's family members and friends. Therefore, the completeness and accuracy of this information are limited by the knowledge of the informant. This may explain

**Comment [SD()]:** Is this too pointed or strong?

**Comment [SD()]:** This is a slightly different way to present this info. What do you think?

**Comment [SD()]:** Is it nationally representative at this point? Or no?

## Structured abstract (241/250 words)

**Background:** Suicide rates have been ~~risking-rising~~ in the United States (U.S.). Examining state-level trends in, and contributing circumstances to, suicide, can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates, ~~overall and by sex and state, by state and sex~~, among people aged ≥10 years, were ~~calculated~~ ~~evaluated~~ using data from the National Vital Statistics System. Changes in rates and state rankings were assessed across six consecutive three-year periods (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013, 2014-2016). Data from the 2015 National Violent Death Reporting System, across 27 states, were analyzed to compare circumstances between suicide decedents with and without known mental health problems.

**Results:** ~~(Average annual percentage change in suicide rates increased significantly in the U.S. overall (25.4%) and in 44 states, with relative increases ranging from 5.9% in Delaware to 57.6% in North Dakota). Statistically significant upward rate trends were identified for 44 states. (For the U.S. overall and for 30 states individually, empirical rates increased by at least 25% over the study period.)~~ People with (46%) and without (54%) known mental health problems experienced a range of contributing circumstances to their suicides, including recent crises and problems related to substance use, relationships, job/financial issues, criminal-legal matters and recent.

**Conclusions:** Suicide rates have risen significantly in the U.S. and across most states from 1999-2016. No single factor alone contributes to suicide.

**Implications for Public Health Practice:** To reverse upward trends in suicide, states can use a population-based public health approach inclusive of evidence-based strategies across multiple levels (individual, family/relationship, community, societal), focused on preventing risk before it starts, identifying and supporting people already at risk, preventing-re-attempts, and caring for survivors after a suicide.

## INTRODUCTION

### BACKGROUND AND PURPOSE (210/250 words) TOTAL COUNT=1900/1800

In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> While overall rates have been declining globally,<sup>2</sup> rates of suicide in the U.S. have increased between 1999 and 2016, among males and females, across racial/ethnic groups, and across urbanization levels.<sup>3,4</sup> Emergency department visits for nonfatal self-harm injuries increased by more than 40% between 2001 and 2015.<sup>5</sup> In 2015, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs.<sup>1</sup> Suicide is rarely caused by one factor, rather, the risks are often numerous and occur at multiple levels--individual, family/relationship, community, and societal.<sup>6</sup> Despite this, ~~prevention primarily centers on mental illness,~~ (e.g., depression bipolar disorder). Other factors associated with suicide include social isolation, economic downturns, access to lethal means (e.g. ~~substances~~, firearms) among people at risk, childhood adversity, lack of coping and problem-solving skills, loss of a friend or family member to suicide, a prior suicide attempt, and unsafe media portrayals, among others.<sup>6</sup> While the Surgeon General called for a comprehensive public health approach to suicide prevention in 1999, to date, most states struggle to make this a reality.<sup>7</sup> To better assist states, this study analyzes trends in state suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

### METHODS (259/250 words)

Comment [snk6]:

This is the key stratification in my view.

Comment [snk6]:

The word "assessed" would also be fine here.

Comment [snk6]:

Probably shouldn't mix the inferential findings with the descriptive findings in the same sentence. Also, we might not be able to afford the word space in the Abstract to talk about individual states.

Comment [snk6]:

And for 29 of these 30 states, the modeled rate trends were also statistically significant. So these two sentences together, while keeping the inferential and descriptive findings separate, provide a scientifically accurate summary.

Comment [SD()]: Need to update

Comment [SD()]: Need reference here.

Comment [SD()]: Do we want to say opioids as an example here instead so that we can tie this in??

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03).<sup>8</sup> Age-specific population estimates were obtained from U.S. Census Bureau / National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods covering years 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics, including precipitating circumstances, of deaths by suicide among decedents with and without known current mental health problems (MHP). Mental health problems are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>9</sup> with the exception of alcohol and other substance dependence (captured in separate variables). NVDRS compiles data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## **RESULTS (696/600 words)**

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rates trends were found to be significantly increasing for 44 states, as well as for the U.S. overall (Table 1). By sex, rate trends were found to be significantly increasing in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known mental health problems (MHP) were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

Although firearms were used most often in both groups, decedents with known MHP died by poisoning more than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

All suicide decedents with known MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had known precipitating circumstances. Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3, 95% CI = 1.2-1.4), and specifically of intimate partner problems (aOR = 1.4, 95%

CI = 1.3-1.5), arguments or conflicts (aOR = 1.4, 95% CI = 1.3-1.5), and having recently perpetrator interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). Two-thirds of decedents with known MHP had a history of MH or substance abuse treatment (67.2%), and were more likely to have any substance abuse problems (31.6% vs. 25%,  $p \leq .01$ ).

Suicide decedents without known MHP had significantly greater odds of other life stressors, such as a criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9), or eviction/loss of home (aOR = 1.4, 95% CI = 1.2-1.6). They had significantly lower odds of recent release from any institution, but when a release was indicated, they were significantly more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-6.3), or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released from an institution, 42.8% release was from a psychiatric institution. Those with known MHP also more frequently had job and/or financial problems (16.8% vs. 15.6%;  $p \leq .05$ ).

Decedents without known MHP had significantly greater odds of a recent/impending crisis (aOR = 1.4, 95% CI = 1.3-1.5). When the type of crisis was known, it was most frequently a problem related to an intimate partner (36.2%), physical health (13.8%), criminal legal issues (13.6%), a family relationship (7.1%), or a job (5.3%). Over one-fourth of decedents with a known MH problem also had recent or impending crises, most frequently related to problems with an intimate partner (34.9%), physical health (12.9%), or a family relationship (8.7%). Decedents without known MHP had significantly greater odds of criminal legal problems (aOR = 1.6, 95% CI = 1.3-1.9), and significantly lowered odds of job-related (aOR = 0.7, 95% CI = 0.5-0.8) crises.

Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

### Conclusions and Comments (735/700 words)

During the time period 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall. Forty-four states saw significant rate increases and one (Nevada) state saw a significant decline. Suicide rates increased by more than 25% in 30 states and upwards of 50% in some.

Among females, rates increased in 43 states and rates among males increased in 34. This signal of increasing vulnerability of females towards suicide aligns with recent reports that identified a 63% increase in middle-aged female suicide rates between 1999-2014 and an annual increase of 18.8% per year in emergency department visits for self-inflicted injuries among young females, aged of 10 and 14, in the period 2009-2015.<sup>3,10</sup> These increases may hint at a narrowing of the suicide gender gap, historically weighted towards males by a ratio of 4-5:1.<sup>11</sup> More research into this troubling trend is needed.

One important factor associated with suicide is mental health problems. Nearly half of people in this study had a known mental health problem. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of mental health and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, much more support for this vulnerable population is needed. This includes the need for broader implementation of affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral therapy.<sup>12</sup> Additionally, greater access to behavioral health providers, especially in underserved areas is needed, as is healthcare systems change that supports suicide prevention and patient safety.<sup>12</sup>

**Comment [SD]:** We also have some additional data that is forthcoming on the types of recent crises, FYI so that may be added as well.

While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did *not* have a known MPH. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence), but also related to other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the abovementioned factors). People with known MHP also experienced life and other stressors apart from their MPH. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%).

These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH treatment alone. These strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills and other pro-social norms, especially early in life to manage everyday stressors and to prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing access to lethal means among people at risk, and creating organizational and workplace policies to promote help-seeking and positive social norms), and supporting people after a suicide has taken place to prevent survivors' risk and to assure safe reporting by the media in order to prevent suicide contagion.<sup>12</sup>

The findings provided of this report are subject to at least three limitations. In four states, Maryland (MD), Utah (UT), Massachusetts (MA), and Rhode Island (RI), state rankings might have been impacted by large proportions of deaths of undetermined intent (MD), or by decreased percentages of undetermined deaths over time (UT, MA, RI). Second, data for state level analyses extend from 1999 to 2016, however, data on circumstances of suicide come from a single year (2015) and encompass only 27 states. Third, abstractors of NVDRS data are limited to data included in the investigative reports they receive. For example, medical and mental health information are not captured directly from medical records but from coroner/medical examiner reports and the decedent's family members and friends. Therefore, knowledge of the informant impacts completeness and accuracy of the information reported. This may explain some of the discrepancy between the prevalence of mental health disorders reported here (54%) and the 90% statistic frequently cited in other studies.<sup>13</sup>

Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just one of many associated factors. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices*<sup>12</sup> and the National Violent Death Reporting System can help states and communities prioritize comprehensive suicide prevention.

Decedents without known MHP had significantly greater odds of criminal legal problems (aOR = 1.6, 95% CI = 1.3-1.9), and significantly lowered odds of job-related (aOR = 0.7, 95% CI = 0.5-0.8) crises.

Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

### **Conclusions and Comments (735/700 words)**

During the time period 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall. Forty-four states saw significant rate increases and one (Nevada) state saw a significant decline. Suicide rates increased by more than 25% in 30 states and upwards of 50% in some.

Among females, rates increased in 43 states and rates among males increased in 34. This signal of increasing vulnerability of females towards suicide aligns with recent reports that identified a 63% increase in middle-aged female suicide rates between 1999-2014 and an annual increase of 18.8% per year in emergency department visits for self-inflicted injuries among young females, aged of 10 and 14, in the period 2009-2015.<sup>3,10</sup> These increases may hint at a narrowing of the suicide gender gap, historically weighted towards males by a ratio of 4-5:1.<sup>11</sup> More research into this troubling trend is needed.

One important factor associated with suicide is mental health problems. Nearly half of people in this study had a known mental health problem. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of mental health and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, much more support for this vulnerable population is needed. This includes the need for broader implementation of affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral therapy.<sup>12</sup> Additionally, greater access to behavioral health providers, especially in underserved areas is needed, as is healthcare systems change that supports suicide prevention and patient safety.<sup>12</sup>

While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did *not* have a known MPH. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence), but also related to other

life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the abovementioned factors). People with known MHP also experienced life and other stressors apart from their MPH. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%).

These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH treatment alone. These strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills and other pro-social norms, especially early in life to manage everyday stressors and to prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing access to lethal means among people at risk, and creating organizational and workplace policies to promote help-seeking and positive social norms), and supporting people after a suicide has taken place to prevent survivors' risk and to assure safe reporting by the media in order to prevent suicide contagion.<sup>12</sup>

The findings provided of this report are subject to at least three limitations. In four states, Maryland (MD), Utah (UT), Massachusetts (MA), and Rhode Island (RI), state rankings might have been impacted by large proportions of deaths of undetermined intent (MD), or by decreased percentages of undetermined deaths over time (UT, MA, RI). Second, data for state level analyses extend from 1999 to 2016, however, data on circumstances of suicide come from a single year (2015) and encompass only 27 states. Third, abstractors of NVDRS data are limited to data included in the investigative reports they receive. For example, medical and mental health information are not captured directly from medical records but from coroner/medical examiner reports and the decedent's family members and friends. Therefore, knowledge of the informant impacts completeness and accuracy of the information reported. This may explain some of the discrepancy between the prevalence of mental health disorders reported here (54%) and the 90% statistic frequently cited in other studies.<sup>13</sup>

Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just one of many associated factors. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices*<sup>12</sup> and the National Violent Death Reporting System can help states and communities prioritize comprehensive suicide prevention.

### Structured abstract (241/250 words)

**Background:** Suicide rates have been rising in the United States (U.S.). Examining state-level trends in, and contributing circumstances to, suicide, can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates, overall and by sex and state, among people aged ≥10 years, were calculated using data from the National Vital Statistics System. Changes in rates and state rankings were assessed across six consecutive three-year periods (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013, 2014-2016). Data from the 2015 from the National Violent Death Reporting System, across 27 states, were analyzed to compare precipitating circumstances between suicide decedents with and without known mental health problems.

**Results:** Average annual percentage change in suicide rates increased significantly in the U.S. overall (25.4%) and in 44 states, with relative increases ranging from 5.9% in Delaware to 57.6% in North Dakota. People with (46%) and without (54%) known mental health problems experienced a range of contributing circumstances contributing to their suicides, including recent crises and problems related to substance use, relationships, job/financial issues, and criminal-legal matters and recent.

**Conclusions:** Suicide rates have risen significantly in the U.S. and across most states from 1999-2016. No single factor alone contributes to suicide. Differing circumstances contribute to suicides among those with and without mental health problems.

**Implications for Public Health Practice:** To reverse upward trends in suicide, states can use a population-based public health approach inclusive of evidence-based strategies across multiple levels (individual, family/relationship, community, societal), focused on preventing risk before it starts, identifying and supporting people already at risk, preventing-re-attempts, and caring for survivors after a suicide.

### INTRODUCTION

#### BACKGROUND AND PURPOSE (210/250 words) TOTAL COUNT=1900/1800

In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> While overall rates have been declining globally,<sup>2</sup> rates of suicide in the U.S. have increased between 1999 and 2016, among males and females, across racial/ethnic groups, and across urbanization levels.<sup>3,4</sup> Emergency department visits for nonfatal self-harm injuries increased by more than 40% between 2001 and 2015.<sup>5</sup> In 2015, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs.<sup>1</sup> Suicide is rarely caused by one factor; rather, the risks are often numerous and occur at multiple levels—individual, family/relationship, community, and societal.<sup>6</sup> Despite this, prevention primarily centers on mental illness, (e.g., depression, bipolar disorder). Other factors associated with suicide include social isolation, economic downturns, access to lethal means (e.g., substances, firearms) among people at risk, childhood adversity, lack of coping and problem-solving skills, loss of a friend or family member to suicide, a prior suicide attempt, and unsafe media portrayals, among others.<sup>6</sup> While the Surgeon General called for a comprehensive public health approach to suicide prevention in 1999, to date, most states struggle to make this a reality.<sup>7</sup> To better assist states, this study analyzes trends in state suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

#### METHODS (259/250 words)

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of*

**Comment [FKA():]** Should we say anything about the time periods we're referring to here?

**Comment [FKA():]** If we have another few words, might want to say that some common and some differing circumstances contribute to suicides of those with and without known mental health problems, since that's a big focus for us. I know we're tight on words, just a suggestion if possible

**Comment [vid5]:** Could we shorten to "primary prevention"?

**Comment [FKA():]** I think a lot of people not familiar with this area think of survivors as people who themselves survived a suicide attempt. Can we clarify with something like (e.g., friends and family of suicide decedents), or something more plain language?

**Comment [SD():]** Need to update

**Comment [SD():]** Need reference here.

**Comment [FKA():]** Probably could cut these examples of diagnoses as long as the reference gets into defining mental illness sufficiently.

**Comment [SD():]** Do we want to say opioids as an example here instead so that we can tie this in??

**Comment [FKA():]** I'd vote to leave it broad, or just consistent with the National Strategy which we reference here.

*Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03).<sup>8</sup> Age-specific population estimates were obtained from U.S. Census Bureau / National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods covering years 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics, including precipitating circumstances, of deaths by suicide among decedents with and without known current mental health problems (MHP). Mental health problems are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>9</sup> with the exception of alcohol and other substance dependence (captured ~~in separate variables~~). NVDRS ~~compiles aggregates~~ data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (696/600 words)

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rates trends ~~were found to be significantly increasing~~ ~~increased significantly~~ for 44 states, as well as for the U.S. overall (Table 1). By sex, rate trends ~~increased significantly~~ ~~were found to be significantly increasing~~ in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known mental health problems (MHP) were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

Although firearms were used most often in both groups, decedents with known MHP died by poisoning more than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

All suicide decedents with known MHP (N=9,407) and approximately 85% without ~~known MHP~~ (N=9,357) had known precipitating circumstances. Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3, 95% CI = 1.2-1.4), ~~and specifically of intimate partner problems~~ (aOR = 1.4, 95% CI = 1.3-1.5), arguments ~~or~~ conflicts (aOR = 1.4, 95% CI = 1.3-1.5), and ~~having recently perpetrated~~ ~~danger~~

interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). Two-thirds of decedents with known MHP had a history of MH or substance abuse treatment (67.2%), and were more likely to have any substance abuse problems (31.6% vs. 25%,  $p \leq .01$ ),

Suicide decedents without known MHP had significantly greater odds of other life stressors, such as a criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9), or eviction/loss of home (aOR = 1.4, 95% CI 1.2-1.6). They had significantly lower odds of recent release from any institution, but when a release was indicated, they were significantly more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-6.3), or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released from an institution, 42.8% ~~release was were~~ from a psychiatric institutions. Those with known MHP also more frequently had job and/or financial problems (16.8% vs. 15.6%;  $p \leq .05$ ).

Decedents without known MHP had significantly greater odds of a recent/impending crisis (aOR = 1.4, 95% CI = 1.3-1.5). When the type of crisis was known, it was most frequently ~~a problem~~ related to an intimate partner (36.2%), physical health (13.8%), criminal legal issues (13.6%), ~~a family relationships~~ (7.1%), or a job (5.3%). Over one-fourth of decedents with a known ~~MHP~~ ~~problem~~ MHP also had recent or impending crises, most frequently related to ~~problems with~~ an intimate partner (34.9%), physical health (12.9%), or ~~a family relationships~~ (8.7%). ~~Decedents without known MHP had significantly greater odds of criminal legal problems crises (aOR = 1.6, 95% CI = 1.3-1.9), and significantly lowered odds of job-related crises (aOR = 0.7, 95% CI = 0.5-0.8) crises.~~

Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

#### Conclusions and Comments (735/700 words)

~~During the time period~~ From 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall. Forty-four states saw significant rate increases and one (Nevada) state saw a significant decline. Suicide rates increased by more than 25% in 30 states and upwards of 50% ~~in some~~.

Among females, rates increased in 43 states and rates among males increased in 34. This signal of increasing vulnerability of females towards suicide aligns with recent reports that identified a 63% increase in middle-aged female suicide rates between 1999-2014 and an annual increase of 18.8% per year in emergency department visits for self-inflicted injuries among young females, aged of 10 and 14, in the period 2009-2015.<sup>3,10</sup> These increases may hint at a narrowing of the suicide gender gap, historically weighted towards males by a ratio of 4-5:1.<sup>11</sup> More research into this troubling trend is needed.

One important factor associated with suicide is mental health problems. Nearly half of people in this study had a known mental health problem. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of mental health and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, much more support for this vulnerable population is needed. This includes the need for broader implementation of affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral therapy.<sup>12</sup> Additionally, greater access to behavioral health providers, especially in underserved areas is needed, as is healthcare systems change that supports suicide prevention and patient safety.<sup>12</sup>

While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did *not* have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner

**Comment [vid5]:** Could probably cut this if we need to for space

**Comment [vid5]:** Maybe we should be more precise

problems, arguments or conflicts, recent perpetration of intimate partner violence), but also related to other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the abovementioned factors). People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%).

These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH treatment alone. These strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills and other pro-social norms, especially early in life to manage everyday stressors and to prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing access to lethal means among people at risk, and creating organizational and workplace policies to promote help-seeking and positive social norms), and supporting people after a suicide has taken place to prevent survivors' risk and to assure safe reporting by the media in order to prevent suicide contagion.<sup>12</sup>

These findings provided of this report are subject to have at least three limitations. In four states, Maryland (MD), Utah (UT), Massachusetts (MA), and Rhode Island (RI), state rankings might have been impacted by large proportions of deaths of undetermined intent (MD), which often represent cases where a suicide determination was judged not to be conclusive, or by decreased percentages of undetermined deaths over time (UT, MA, RI). Second, NVDRS is not yet nationally representative. Currently, 40 states, the District of Columbia, and Puerto Rico participate in NVDRS, but the most recent available data year includes 27 states as others joined the system later data for state level analyses extend from 1999 to 2016, however, data on circumstances of suicide come from a single year (2015) and encompass only 27 states. Third, abstractors of NVDRS data are limited to data included in the investigative reports they receive. For example, medical and mental health information are not captured directly from medical records but from informants (e.g., family, friends) via coroner/medical examiner reports and the decedent's family members and friends. Therefore, knowledge of the informant impacts completeness and accuracy of the information reported. This may explain some of the discrepancy between the prevalence of mental health disorders reported here (54%) and the 90% statistic frequently cited in other studies.<sup>13</sup>

Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just one of many associated factors. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices*<sup>12</sup> and the National Violent Death Reporting System can help states and communities prioritize comprehensive suicide prevention.

**Comment [vid5]:** Wondering if instead of recapping results, we could comment on the profound and not often discussed impact that life stressors, especially those that rise to the level of a crisis, can have. The research that shows the time amount of deliberation (which is often very low) may also be helpful to cite here, as these types of stressors/crises can represent short-term problems (vs. longer term problems such as chronic mental illness)

**Comment [vid5]:** Similarly, wondering if we could condense this instead of reiterating some of these results and instead comment on the concept of "functional impairment," as a reason why people with mental health problems might have more job/financial problems (e.g., they often have more inconsistent work histories as a result of trying to cope)

**Comment [vid5]:** I know we don't want to really be adding words – but I thought this is one thing that may not be obvious to everyone (why deaths of undetermined intent would affect suicide counts/rates). See what you think, and if we can't get the text in, maybe we could sneak a footnote in ☺

**Comment [SD]:** Is it nationally representative at this point? Or no?

**Comment [vid5]:** Some suggested rephrasing here, because I don't want to trigger questions about why we would only use one data year of NVDRS data. We have good reasons – more states, and for the state level analyses we were looking at trends and therefore needed more years. However, wondering if we could simplify this to just be about NVDRS

**Comment [vid5]:** Just to give our data enough credit, though, I am wondering if the 90% estimates could also be driven up by small or very selective samples. Was going to look into this but not sure what the reference is. Little wary of making it sound like theirs is the gold standard.

DRAFT

## Structured abstract (241/250 words)

**Background:** Suicide rates have been rising in the United States (U.S.). Examining state-level trends in, and contributing circumstances to, suicide, can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates, overall and by sex and state, among people aged ≥10 years, were calculated (evaluated) using data from the National Vital Statistics System. Changes in rates and state rankings were assessed across six consecutive three-year periods (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013, 2014-2016). Data from the 2015 from the National Violent Death Reporting System, across 27 states, were analyzed to compare precipitating circumstances between suicide decedents with and without known mental health problems.

**Results:** Statistically significant upward rate trends were identified for 44 states. (For the U.S. overall and for 30 states individually, empirical rates increased by at least 25% over the study period.) Average annual percentage change in suicide rates (increased significantly) in the U.S. overall (25.4%) and in 44 states, with relative increases ranging from 5.9% in Delaware to 57.6% in North Dakota. People with (46%) and without (54%) known mental health problems experienced a range of contributing circumstances contributing to their suicides, including recent crises and problems related to substance use, relationships, job/financial issues, and criminal-legal matters and recent.

**Conclusions:** Suicide rates have risen significantly in the U.S. and across most states from 1999-2016. (No single factor alone contributes to suicide.) Differing circumstances contribute to suicides among those with and without mental health problems.

**Implications for Public Health Practice:** To reverse upward trends in suicide, states can use a population-based public health approach inclusive of evidence-based strategies across multiple levels (individual, family/relationship, community, societal), focused on (preventing risk before it starts), identifying and supporting people already at risk, preventing-re-attempts, and caring for (survivors) after a suicide.

## INTRODUCTION

### BACKGROUND AND PURPOSE (210/250 words) TOTAL COUNT=1900/1800

In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> While overall rates have been declining globally,<sup>2</sup> rates of suicide in the U.S. have increased between 1999 and 2016, among males and females, across racial/ethnic groups, and across urbanization levels.<sup>3,4</sup> Emergency department visits for nonfatal self-harm injuries increased by more than 40% between 2001 and 2015.<sup>5</sup> In 2015, suicides and self-harm injuries cost the nation more than (\$69 billion) in direct medical and work loss costs.<sup>1</sup> Suicide is rarely caused by one factor; rather, the risks are often numerous and occur at multiple levels--individual, family/relationship, community, and societal.<sup>6</sup> Despite this, (prevention primarily centers on mental illness.) (e.g., depression, bipolar disorder). Other factors associated with suicide include social isolation, economic downturns, access to lethal means (e.g. substances, firearms) among people at risk, childhood adversity, lack of coping and problem-solving skills, loss of a friend or family member to suicide, a prior suicide attempt, and unsafe media portrayals, among others.<sup>6</sup> While the Surgeon General called for a comprehensive public health approach to suicide prevention in 1999, to date, most states struggle to make this a reality.<sup>7</sup> To better assist states, this study analyzes trends in state suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

### METHODS (259/250 words)

**Comment [SD():** Scott's comment: This is the key stratification in my view.

**Comment [SD():** Scott's comment: The word assessed would also be fine here.

**Comment [snk6]:** And for 29 of these 30 states, the modeled rate trends were also statistically significant. So these two sentences together, while keeping the inferential and descriptive findings separate, provide a scientifically accurate summary.

**Comment [FKA():** Should we say anything about the time periods we're referring to here?

**Comment [SD():** Scott's comment: Probably shouldn't mix the inferential findings with the descriptive findings in the same sentence. Also, we might not be able to afford the word space in the Abstract to talk about individual states.

**Comment [FKA():** If we have another few words, might want to say that some common and some differing

**Comment [vid5]:** Could we shorten to "primary prevention"?

**Comment [CA]:** I like "primary prevention"

**Comment [FKA():** I think a lot of people not familiar with this area think of survivors as people who themselves

**Comment [SD():** Need to update

**Comment [SD():** Need reference here.

**Comment [CA]:** Options: -Rosenman SJ. Preventing suicide: What will work and what will not. MJA.

**Comment [FKA():** Probably could cut these examples of diagnoses as long as the reference gets into defining mental

**Comment [SD():** Do we want to say opioids as an example here instead so that we can tie this in??

**Comment [FKA():** I'd vote to leave it broad, or just consistent with the National Strategy which we reference here.

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of-death codes X60-X84, Y87.0, \*U03).<sup>8</sup> Age-specific population estimates were obtained from U.S. Census Bureau / National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods covering years 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics, including precipitating circumstances, of deaths by suicide among decedents with and without known current mental health problems (MHP). Mental health problems are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>9</sup> with the exception of alcohol and other substance dependence (captured ~~in separate variables~~). NVDRS ~~compiles aggregates~~ data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (696/600 words)

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rates trends ~~were found to be significantly increasing~~ increased significantly for 44 states, as well as for the U.S. overall (Table 1). By sex, rate trends ~~increased significantly were found to be significantly increasing~~ in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known mental health problems (MHP) were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

Although firearms were used most often in both groups, decedents with known MHP died by poisoning more than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

All suicide decedents with known MHP (N=9,407) and approximately 85% without ~~known MHP~~ (N=9,357) had known precipitating circumstances. Decedents without known MHP had significantly greater odds of any type of

relationship problem (aOR = 1.3, 95% CI = 1.2-1.4), and specifically of intimate partner problems (aOR = 1.4, 95% CI = 1.3-1.5), arguments/~~of~~ conflicts (aOR = 1.4, 95% CI = 1.3-1.5), and ~~having recently perpetrated~~ ~~ing~~ ~~of~~ interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). Two-thirds of decedents with known MHP had a history of MH or substance abuse treatment (67.2%), and were more likely to have any substance abuse problems (31.6% vs. 25%,  $p \leq .01$ ),

Suicide decedents without known MHP had significantly greater odds of other life stressors, such as a criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9), or eviction/loss of home (aOR = 1.4, 95% CI 1.2-1.6). They had significantly lower odds of recent release from any institution, but when a release was indicated, they were significantly more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-6.3), or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released from an institution, 42.8% ~~release was~~ ~~were~~ from a psychiatric institutions. Those with known MHP also more frequently had job and/or financial problems (16.8% vs. 15.6%;  $p \leq .05$ ).

Decedents without known MHP had significantly greater odds of a recent/impending crisis (aOR = 1.4, 95% CI = 1.3-1.5). When the type of crisis was known, it was most frequently a ~~problem~~-related to an intimate partner (36.2%), physical health (13.8%), criminal legal issues (13.6%), a family relationships (7.1%), or a job (5.3%). Over one-fourth of decedents with a known ~~MHP~~ ~~problem~~ ~~MHP~~ also had recent or impending crises, most frequently related to ~~problems with~~ an intimate partner (34.9%), physical health (12.9%), or a family relationships (8.7%). Decedents without known MHP had significantly greater odds of criminal legal ~~problems~~ ~~crises~~ (aOR = 1.6, 95% CI = 1.3-1.9), and significantly lowered odds of job-related ~~crises~~ (aOR = 0.7, 95% CI = 0.5-0.8) ~~crises~~.

Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

#### Conclusions and Comments (735/700 words)

~~During the time period~~From 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall. Forty-four states saw significant rate increases and one (Nevada) state saw a significant decline. Suicide rates increased by more than 25% in 30 states and upwards of 50% ~~(in some)~~.

Among females, rates increased in 43 states and rates among males increased in 34. This signal of increasing vulnerability of females towards suicide aligns with recent reports that identified a 63% increase in middle-aged female suicide rates between 1999-2014 and an annual increase of 18.8% per year in emergency department visits for self-inflicted injuries among young females, aged of 10 and 14, in the period 2009-2015.<sup>3,10</sup> These increases may hint at a narrowing of the suicide gender gap, historically weighted towards males ~~by a ratio of 4-5:1~~.<sup>11</sup> More research into this troubling trend is needed.

One important factor associated with suicide is mental health problems. Nearly half of people in this study had a known mental health problem. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of mental health and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, much more support for this vulnerable population is needed. This includes the need for broader implementation of affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral therapy.<sup>12</sup> Additionally, greater access to behavioral health providers, especially in underserved areas is needed, as is healthcare systems change that supports suicide prevention and patient safety.<sup>12</sup>

Comment [vid5]: Could probably cut this if we need to for space

Comment [vid5]: Maybe we should be more precise

Comment [CA]: Maybe could leave out ratio to save space.

While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did *not* have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence), but also related to other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the abovementioned factors). People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%).

These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH treatment alone. These strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills and other pro-social norms, especially early in life to manage everyday stressors and to prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing access to lethal means among people at risk, and creating organizational and workplace policies to promote help-seeking and positive social norms), and supporting people after a suicide has taken place to prevent survivors' risk and to assure safe reporting by the media in order to prevent suicide contagion.<sup>12</sup>

These findings provided of this report are subject to have at least three limitations. In four states, Maryland (MD), Utah (UT), Massachusetts (MA), and Rhode Island (RI), state rankings might have been impacted by large proportions of deaths of undetermined intent (MD), which often represent cases where a suicide determination was judged not to be conclusive, or by decreased percentages of undetermined deaths over time (UT, MA, RI). Second, NVDRS is not yet nationally representative. Currently, 40 states, the District of Columbia, and Puerto Rico participate in NVDRS, but the most recent available data year includes 27 states as others joined the system later data for state level analyses extend from 1999 to 2016, however, data on circumstances of suicide come from a single year (2015) and encompass only 27 states. Third, abstractors of NVDRS data are limited to data included in the investigative reports they receive. For example, medical and mental health information are not captured directly from medical records but from informants (e.g., family, friends) via coroner/medical examiner reports and the decedent's family members and friends. Therefore, knowledge of the informant impacts completeness and accuracy of the information reported. This may explain some of the discrepancy between the prevalence of mental health disorders reported here (54%) and the 90% statistic frequently cited in other studies.<sup>13</sup>

Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just one of many associated factors. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices*<sup>12</sup> and the National Violent Death Reporting System can help states and communities prioritize comprehensive suicide prevention.

**Comment [vid5]:** Wondering if instead of recapping results, we could comment on the profound and not often discussed impact that life stressors, especially those that rise to the level of a crisis, can have. The research that shows the time amount of deliberation (which is often very low) may also be helpful to cite here, as these types of stressors/crises can represent short-term problems (vs. longer term problems such as chronic mental illness)

**Comment [vid5]:** Similarly, wondering if we could condense this instead of reiterating some of these results and instead comment on the concept of "functional impairment," as a reason why people with mental health problems might have more job/financial problems (e.g., they often have more inconsistent work histories as a result of trying to cope)

**Comment [vid5]:** I know we don't want to really be adding words – but I thought this is one thing that may not be obvious to everyone (why deaths of undetermined intent would affect suicide counts/rates). See what you think, and if we can't get the text in, maybe we could sneak a footnote in ☺

**Comment [SD]:** Is it nationally representative at this point? Or no?

**Comment [vid5]:** Some suggested rephrasing here, because I don't want to trigger questions about why we would only use one data year of NVDRS data. We have good reasons – more states, and for the state level analyses we were looking at trends and therefore needed more years. However, wondering if we could simplify this to just be about NVDRS

**Comment [vid5]:** Just to give our data enough credit, though, I am wondering if the 90% estimates could also be driven up by small or very selective samples. Was going to look into this but not sure what the reference is. Little wary of making it sound like theirs is the gold standard.

**From Katie:**

I went through the latest draft w/Alex's comments, comparing the results and discussion. Most lined up, although there were a few places where I noticed some mismatch (" " is from the draft, bold are my comments):

"From 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall." **We give the national (overall) number only in the abstract, not in the results.**

"Suicide rates increased by more than 25% in 30 states and upwards of 50% in some". **We only mention one (North Dakota) that is over 50% in the results (rather than "some").**

"While two-thirds of people with MHP had a history of mental health and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, much more support for this vulnerable population is needed." **The highlighted point is only in the table right now– could add to results text.**

"While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did *not* have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence)..." **Didn't notice this the first time around, but the highlighted portion should read "recent perpetration of *interpersonal* violence" – that variable is not specific to IPV.**

"People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%)." **The numbers in the highlighted portion are in the table, but not specifically cited in the results (because we report odds ratios instead).**

## Structured abstract (241/250 words)

**Background:** Suicide rates have been rising in the United States (U.S.). Examining state-level trends in, and contributing circumstances to, suicide, can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates, overall and by state and sex and state, among people aged ≥10 years, were calculated/evaluated using data from the National Vital Statistics System. Changes in rates and state rankings were assessed across six consecutive three-year periods (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013, 2014-2016). Data from the 2015 from the National Violent Death Reporting System, across 27 states, were analyzed to compare precipitating circumstances between suicide decedents with and without known mental health problems.

**Results:** Statistically significant upward rate trends were identified for 44 states. (For the U.S. overall and for 30 states individually, empirical rates increased by at least 25% over the study period.) Average annual percentage change in suicide rates (increased significantly) in the U.S. overall (25.4%) and in 44 states, with relative increases ranging from 5.9% in Delaware to 57.6% in North Dakota. People with (46%) and without (54%) known mental health problems experienced a range of contributing circumstances contributing to their suicides, including recent crises and problems related to substance use, relationships, job/financial issues, and criminal-legal matters and recent.

**Conclusions:** Suicide rates have risen significantly in the U.S. and across most states from 1999-2016. (No single factor alone contributes to suicide.) Differing circumstances contributing to suicides differ among those with and without known health problems.

**Implications for Public Health Practice:** To reverse upward trends in suicide, states can use a population-based public health approach inclusive of evidence-based strategies across multiple levels (individual, family/relationship, community, societal), focused on preventing risk before it starts, identifying and supporting people already at risk, preventing-re-attempts, and caring for/supporting survivors after a suicide decedents' surviving loved ones.

## INTRODUCTION

### BACKGROUND AND PURPOSE (210/250 words) TOTAL COUNT=1900/1800

In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> While overall rates have been declining globally,<sup>2</sup> rates of suicide in the U.S. have increased between 1999 and 2016, among males and females, across racial/ethnic groups, and across urbanization levels.<sup>3,4</sup> Emergency department visits for nonfatal self-harm injuries increased by more than 40% between 2001 and 2015.<sup>1</sup> In 2015, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs.<sup>1</sup> Suicide is rarely caused by one factor; rather, the risks are often numerous and occur at multiple levels--individual, family/relationship, community, and societal.<sup>5</sup> Despite this, prevention primarily centers on mental illness (e.g., depression, bipolar disorder). Other factors associated with suicide include social isolation, economic downturns, access to lethal means (e.g. substances, firearms) among people at risk, childhood adversity, lack of poor coping and problem-solving skills, loss of a friend or family member loved one to suicide, a prior suicide attempt, and unsafe media portrayals, among others.<sup>5</sup> While Although the Surgeon General called for a comprehensive public health approach to suicide prevention in 1999, to date, most states struggle to make this a reality.<sup>6</sup> To better assist states, this study analyzes trends in state suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

### METHODS (259/250 words)

**Comment [SD():** Scott's comment: This is the key stratification in my view.

**Comment [SD():** Scott's comment: The word assessed would also be fine here.

**Comment [snk6]:** And for 29 of these 30 states, the modeled rate trends were also statistically significant. So these two sentences together, while keeping the inferential and descriptive findings separate, provide a scientifically accurate summary.

**Comment [FKA():** Should we say anything about the time periods we're referring to here?

**Comment [SD():** Scott's comment: Probably shouldn't mix the inferential findings with the descriptive findings in

**Comment [FKA():** If we have another few words, might want to say that some common and some differing

**Comment [vid5]:** Could we shorten to "primary prevention"?

**Comment [CA]:** I like "primary prevention"

**Comment [FKA():** I think a lot of people not familiar with this area think of survivors as people who themselves

**Comment [HK():** I pose a solution to Katie's question here.

**Comment [SD():** Need to update

**Comment [HK():** Should we add "treating" before mental illness?

**Comment [SD():** Need reference here.

**Comment [CA]:** Options: -Rosenman SJ. Preventing suicide: What will work and what will not. MIA

**Comment [FKA():** Probably could cut these examples of diagnoses as long as the reference gets into defining mental

**Comment [SD():** Do we want to say opioids as an example here instead so that we can tie this in??

**Comment [FKA():** I'd vote to leave it broad, or just consistent with the National Strategy which we reference here

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03). Age-specific population estimates were obtained from U.S. Census Bureau / National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods covering years from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics including precipitating circumstances, of deaths by suicide among decedents with and without known current mental health problems (MHP). Mental health problems MHP are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>7</sup> with the exception of alcohol and other substance dependence (captured in separate variables). NVDRS compiles aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

#### RESULTS (696/600 words)

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rate trends indicate increased significantly significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends increased-indicate by increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known mental health problems (MHP) were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

Although firearms were used most often in both groups, decedents with known MHP died by poisoning more than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

Comment [HK]: I think you can delete this

All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had known precipitating circumstances. Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3, 95% CI = 1.2-1.4), ~~specifically intimate partner problems~~ (aOR = 1.4, 95% CI = 1.3-1.5), arguments ~~conflicts~~ (aOR = 1.4, 95% CI = 1.3-1.5), and ~~recently perpetrated~~ or interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). Two-thirds of decedents with known MHP had a history of MH or substance abuse treatment (67.2%); and were more likely to have any substance abuse problems (31.6% vs. 25%,  $p \leq .01$ ),

Suicide decedents without known MHP had significantly greater odds of other life stressors, such as a criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9); or eviction/loss of home (aOR = 1.4, 95% CI 1.2-1.6). They had significantly lower odds of recent release from any institution, but when a release was indicated, they were significantly more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-6.3), or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released from an institution, 42.8% ~~from~~ from psychiatric institution. Those with known MHP also more frequently had job and/or financial problems (16.8% vs. 15.6%;  $p \leq .05$ ).

Decedents without known MHP had significantly greater odds of a recent/impending crisis (aOR = 1.4, 95% CI = 1.3-1.5). When the type of crisis was known, it was most frequently ~~related~~ related to an intimate partner (36.2%), physical health (13.8%), criminal legal ~~issues~~ (13.6%), family relationships (7.1%), or a job (5.3%) ~~problem~~. Over one-fourth of decedents with a known ~~intimate partner~~ also had recent or impending crises, most frequently related to ~~an intimate partner~~ an intimate partner (34.9%), physical health (12.9%), or a family relationship (8.7%). Decedents without known MHP had significantly greater odds of criminal legal ~~problems~~ (aOR = 1.6, 95% CI = 1.3-1.9), and significantly lowered odds of job-related ~~problems~~ (aOR = 0.7, 95% CI = 0.5-0.8).

Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

#### Conclusions and Comments (735/700 words)

~~From 1999-2016~~ 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall. Forty-four states saw significant rate increases, and one (Nevada) state saw a significant decline. Suicide rates increased by more than 25% in 30 states and upwards of 50% ~~in some~~.

~~Among females, rates increased in 43 states among females and rates among males increased in 34 states among males.~~ This signal of increasing vulnerability to suicide among females towards suicide aligns with recent reports ~~that identified indicating~~ a 63% increase in middle-aged female suicide rates between 1999-2014 and an annual increase of 18.8% per year in emergency department visits for self-inflicted injuries among young females, aged ~~of 10 and 14, in the period from~~ 2009-2015.<sup>3,8</sup> These increases may hint at a narrowing of the suicide gender gap, historically weighted towards males ~~by a ratio of 4-5:1~~.<sup>9</sup> More research into this troubling trend is needed.

One important factor associated with suicide is ~~mental health problems~~ MHP. Nearly half of people in this study had a known ~~mental health problem~~ MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of ~~mental health~~ MH and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, much more support for this vulnerable population is needed. This includes the need for broader implementation of affordable and evidence-based treatments, such as doctor-patient collaborative

**Comment [HK]:** Can you say this? Wouldn't saying this imply that if IPP is checked as a precipitating factor, then relationship problems also has to be checked? Is that how NVDRS coding of IPP works? I thought these two categories were mutually exclusive in that IPP could be checked without relationship problems being checked.

This could be easily changed by just removing "specifically"

**Comment [vid5]:** Could probably cut this if we need to for space

**Comment [vid5]:** Maybe we should be more precise

**Comment [CA]:** Maybe could leave out ratio to save space.

care models and cognitive-behavioral therapy.<sup>10</sup> Additionally, greater access to behavioral health providers, especially in underserved areas is needed, as is healthcare systems change that supports suicide prevention and patient safety.<sup>10</sup>

While MHP are a significant contributor to suicide, 54% of suicide decedents in ~~the current~~ this study did not have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence), but also related to other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the abovementioned factors). People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%).

These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH treatment alone. ~~These Prevention~~ strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills and other pro-social norms, especially early in life to manage everyday stressors and ~~to~~ prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing access to lethal means among people at risk, and creating organizational and workplace policies to promote help-seeking and positive social norms), and supporting people after a suicide has taken place to prevent survivors' risk and to assure safe reporting by the media in order to prevent suicide contagion.<sup>10</sup>

The ~~35~~ findings ~~provided of this report are subject to~~ at least three limitations. In four states, Maryland (MD), Utah (UT), Massachusetts (MA), and Rhode Island (RI), state rankings might have been impacted by large proportions of deaths of undetermined intent (~~MD~~), ~~or by decreased percentages of undetermined deaths over time (UT, MA, RI).~~ Second, ~~NVDRS is not yet nationally representative. Currently, 40 states, the District of Columbia, and Puerto Rico participate in NVDRS, but the most recent available data year includes 27 states as others joined the system later data for state-level analyses covered from 2009 to 2015, however, data on circumstances of suicide come from a single year (2015) and are missing only 17 states.~~ Third, abstractors of NVDRS data are limited to data included in the investigative reports ~~they receive~~. For example, medical and ~~mental health~~ MH information are not captured directly from medical records but from informants (e.g. family, friends) via coroner/medical examiner reports ~~and the decedent's family members and friends~~. Therefore, knowledge of the informant impacts completeness and accuracy of the information reported. This may explain some of the discrepancy between the prevalence of mental health disorders reported here (54%) and the 90% statistic frequently cited in other studies.<sup>(11)</sup>

Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just one of many ~~associated factors~~. Resources such as CDC's Preventing Suicide: a Technical Package of Policies, Programs, and Practices<sup>11</sup> and ~~data from the National Violent Death Reporting System~~ NVDRS can help states and communities prioritize comprehensive suicide prevention.

**Comment [vid5]:** Wondering if instead of recapping results, we could comment on the profound and not often discussed impact that life stressors, especially those that rise to the level of a crisis, can have. The research that shows the time amount of deliberation (which is often very low) may also be helpful to cite here, as these types of stressors/crises can represent short-term problems (vs. longer term problems such as chronic mental illness)

### **From Katie:**

I went through the latest draft w/Alex's comments, comparing the results and discussion. Most lined up, although there were a few places where I noticed some mismatch ("" is from the draft, bold are my comments):

"From 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall." **We give the national (overall) number only in the abstract, not in the results.**

“Suicide rates increased by more than 25% in 30 states and upwards of 50% in some”. **We only mention one (North Dakota) that is over 50% in the results (rather than “some”).**

“While two-thirds of people with MHP had a history of mental health and/or substance abuse treatment and **over half were currently in treatment at the time of their deaths**, much more support for this vulnerable population is needed.” **The highlighted point is only in the table right now– could add to results text.**

“While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did *not* have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, **recent perpetration of intimate partner violence**)...” **Didn’t notice this the first time around, but the highlighted portion should read “recent perpetration of *interpersonal* violence” – that variable is not specific to IPV.**

“People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. **Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%).**” **The numbers in the highlighted portion are in the table, but not specifically cited in the results (because we report odds ratios instead).**

**Structured abstract (241/250 words)**

**Background:** Suicide rates have been rising in the United States (U.S.). Examining state-level trends in, and contributing circumstances to, suicide, can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates, overall and by sex and state, among people aged ≥10 years, were ~~assessed~~ calculated ~~(using)~~ using data from the National Vital Statistics System. Changes in rates and state rankings were ~~examined~~ across six consecutive three-year periods (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013, 2014-2016). Data from ~~the~~ 2015 from the National Violent Death Reporting System, across 27 states, were analyzed to ~~compare~~ examine precipitating circumstances ~~among~~ between suicide decedents with and without known mental health problems.

**Results:** Statistically significant ~~rate increases~~ ~~upward rate trends~~ were identified from 44 states. ~~For the U.S. overall and for 30 states individually, (suicide) rates increased by at least 25% over the study period. (Average annual percentage change in suicide rates increased significantly in the U.S. overall (25.4%) and in 44 states, with relative increases ranging from 5.9% in Delaware to 57.6% in North Dakota.) People with (45%) and without known mental health problems (54%) were more ( ) to experience severe contributing circumstances than those with mental health problems (45%), including relationship problems (45.1% and 49.6%), life stressors (54.2% and 46.7%), and recent crises (32.9% and 25.0, respectively).~~ However, these and other circumstances occurred frequently for both groups. Known mental health problems experienced a range of contributing circumstances contributing to their suicides, including recent crises and problems related to substance use, relationships, job/financial issues, and criminal/legal matters, and recent

**Conclusions:** Suicide rates have risen significantly in the U.S. and across most states from 1999-2016. ~~(No single factor alone contributes to suicide.) Differing (circumstances) contributing to suicides extend beyond mental health problems among those with and without mental health problems.~~

**Implications for Public Health Practice:** To reverse upward trends in suicide, states can use a population-based public health approach ~~inclusive of evidence-based strategies based on the best available evidence~~ across multiple levels (individual, family/relationship, community, societal), focused on preventing risk before it starts, identifying and supporting people already at risk, preventing reattempts, and ~~caring for~~ supporting survivors ~~after a suicide~~ ~~decedents' surviving loved ones.~~

**INTRODUCTION****BACKGROUND AND PURPOSE (210/250 words) TOTAL COUNT=1900/1800**

In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> ~~While overall rates have been declining, (state) rates of suicide rates in the U.S. have increased between 1999 and 2016, among males and females, across racial/ethnic groups, and across urbanization levels.<sup>2,4</sup> Emergency department visits for nonfatal self-harm injuries increased by more than 40% between 2001 and 2015.<sup>5</sup> In 2015, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs.<sup>1</sup> Suicide is rarely caused by one factor; rather, the risks are often numerous and occur at multiple levels—individual, family/relationship, community, and societal.<sup>6</sup> Despite this, prevention primarily centers on mental illness (e.g., depression, bipolar disorder). Other factors associated with suicide include social and isolation, economic problems, ~~downward~~, access to lethal means (e.g. substances, firearms) among people at risk, ~~and~~ ~~adversity~~ ~~lack of~~ coping and problem-solving skills, ~~and~~ ~~loss of a~~ friend or family member ~~loved one to~~ ~~suicide~~, a prior suicide attempt, ~~and~~ ~~unsafe means~~ ~~portable~~, among others.<sup>6</sup> ~~While~~ ~~Although~~ the Surgeon General called for a comprehensive public health approach to suicide prevention in 1999, to date, most states~~

## METHODS (259/250 words)

Suicide rate estimates and trend analyses ~~exclude data for persons <10 years old.~~ Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03).<sup>8</sup> Age-specific population estimates were obtained from U.S. Census Bureau / National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods ~~covering years from~~ 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to ~~the characteristics, including precipitating circumstances, of~~ deaths by suicide among decedents with and without known current mental health problems (MHP). ~~Mental health problems~~ MHP are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>9</sup> with the exception of alcohol and other substance dependence (captured ~~in separate variables~~). NVDRS ~~compiles aggregates~~ data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (696/600 words)

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rates trends ~~were found to be significantly increasing~~ increased significantly for 44 states, as well as for the U.S. overall (Table 1). By sex, rate trends ~~increased significantly were found to be significantly increasing~~ in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known ~~mental health problems~~ (MHP) were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI =

**Comment [tgs9]:** I feel like we need a point like this to set up why we are examining those with and without mental health problems separately.

**Comment [IAZ():** There might not be enough room for an additional reference, but might want to consider including one here to highlight the rationale for excluding persons under 10 years old.

**Comment [HK():** I think you can delete this

2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

Although firearms were used most often in both groups, decedents with known MHP died by poisoning more than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

All suicide decedents with known MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had precipitating circumstances information. ~~Two-thirds of decedents with known MHP had a history of MH or substance abuse treatment (67.2%) and were more likely to have any substance abuse problems (31.6% vs. 25%, p < .01).~~

Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3, 95% CI = 1.2-1.4), and specifically of intimate partner problems (aOR = 1.4, 95% CI = 1.3-1.5), arguments/ or conflicts (aOR = 1.4, 95% CI = 1.3-1.5), and having recently perpetrated or interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). ~~They also two-thirds of decedents with known MHP had a history of MH or substance abuse treatment (67.2%) and were more likely to have any substance abuse problems (31.6% vs. 25%, p < .01).~~

~~Suicide decedents without known MHP had significantly greater odds of other life stressors, such as a criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9), or eviction/loss of home (aOR = 1.4, 95% CI = 1.2-1.6), and were also more likely to have a crisis within the preceding or upcoming two weeks (aOR = 1.4, 95% CI = 1.3-1.5). Among both groups, the most common crises were intimate partner (13.6%) and physical health (13.4%) problems.~~

~~Decedents without known MHP had significantly lower odds of recent release from any institution, but when a release was indicated, they were significantly more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-6.3), or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released from an institution (10.2%), 42.8% release was from a psychiatric institutions. Those with known MHP also more frequently had physical or financial problems (16.2% vs. 15.8%, p < .05).~~

~~Decedents without known MHP had significantly greater odds of a recent/imminent crisis (aOR = 1.3, 95% CI = 1.2-1.5). When the type of crisis was known, it was most frequently a problem related to an intimate partner (36.2%), physical health (13.3%), criminal legal issues (13.3%), a family relationships (7.1%), or a job (5.3%) problem. Over one-fourth of decedents with a known MH problem/MHP also had recent or impending crises, most frequently related to problems with an intimate partner (34.3%), physical health (13.0%), or a family relationships (8.2%). Decedents with known MHP had significantly greater odds of imminent legal problems (aOR = 1.3, 95% CI = 1.1-1.5), and significantly increased odds of not released from an institution (aOR = 1.2, 95% CI = 1.1-1.3).~~

Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%, p < .01) and attempts (29.4% vs. 10.3%, p < .01).

### Conclusions and Comments (735/700 words)

During the time period From 1999-2016, age-adjusted suicide rates among people ≥ 10 years increased 25.4% overall. Forty-four states saw significant rate increases, and one (Nevada) state saw a significant decline. Suicide rates increased by more than 25% in 30 states and upwards of 50% in ~~some~~ (North Dakota).

**Comment [tgs9]:** Suggestion to avoid saying "known" again. Can just use "information"

**Comment [tgs9]:** Suggest moving this sentence here to improve the flow.

**Comment [HK]:** Can you say this? Wouldn't saying this imply that if IPP is checked as a precipitating factor, then relationship problems also has to be checked? Is that how NVDRS coding of IPP works? I thought these two categories were mutually exclusive in that IPP could be checked without relationship problems being checked.

This could be easily changed by just removing "specifically"

**Comment [tgs9]:** I suggest moving this point here for flow. I think we can shorten it in this way to save on words and to focus on the fact that the most common crises applied to both groups. This helps set up our discussion.

**Comment [vid5]:** Could probably cut this if we need to for space

**Comment [vid5]:** Maybe we should be more precise

**Comment [tgs9]:** Why not give the number?

**Comment [IAZ]:** Need to take out "some" here because North Dakota is the only state over the 50% mark.

Among females (rates increased in 43 states among females and rates among males increased in 34 states among males). This signals of increasing vulnerability to suicide among females towards suicide signs with recent reports that identified indicating a 64% increase in (middle-aged female suicide rates between 1999-2014) and an annual increase of 19.2% per year in emergency department visits for self-inflicted injuries among young females aged of 10 and 14, in the period from 2009-2015.<sup>10</sup> These increases may hint at a narrowing of the suicide gender gap, historically weighted towards males (prevalence of 1.2%).<sup>11</sup> More research into this troubling trend is needed.

One important factor associated with suicide is mental health problems (MHP). Nearly half of suicide decedents in NVDRS people in this study had a known mental health problem (MHP). This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of mental health (MH) and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, additional evidence-based support could help address the needs of for this vulnerable population is needed. This includes the need for broader implementation of affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral therapy.<sup>12</sup> Additionally, greater access to behavioral health providers, especially in underserved areas is important need, as is healthcare systems change that supports suicide prevention and patient safety.<sup>12</sup>

While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did not have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence), but also related to other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the abovementioned factors). People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (15.4%), physical health problems (11.4%), and recent or impending crises (10.1%).

These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH treatment alone. These prevention strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills and other pro-social norms, especially early in life to manage everyday stressors and to prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing access to lethal means among people at risk, and creating organizational and workplace policies to promote help-seeking and positive social norms), and supporting people after a suicide has taken place to prevent survivors' risk, and to assure safe reporting by the media in order to prevent suicide contagion.<sup>12</sup>

These findings provided of this report are subject to have at least three limitations. In four states (Maryland (MD), Utah (UT), Massachusetts (MA), and Rhode Island (RI)), state rankings might have been impacted by large proportions of deaths of undetermined intent (MD), (which were somewhat lower than expected) or by decreased percentages of undetermined deaths over time (UT, MA, RH), which likely reflect some unrecognized suicides. Second, NVDRS is not yet nationally representative. Currently, 40 states, the District of Columbia, and Puerto Rico participate in NVDRS. This study used the most current report available data available and year includes 27 states that represent half (49.6%) of the U.S. (population). Others joined the system later data for state level analyses extend from 1999 to 2016, however, data on circumstances of suicide come from a single year (2015) and encompass only 27 states.

**Comment [CA]:** Maybe could leave out ratio to save space.

**Comment [tgs9]:** This paragraph could be shortened a lot. We could have tested the change in the sex gap but we did not present this so the point seems tangential. Also, we also don't talk about sex differences in circumstances or prevention strategies so this text could get the reader wondering about issues that we don't discuss.

**Comment [vid5]:** Wondering if instead of recapping results, we could comment on the profound and not often discussed impact that life stressors, especially those that rise to the level of a crisis, can have. The research that shows the time amount of deliberation (which is often very low) may also be helpful to cite here, as these types of stressors/crises can represent short-term problems (vs. longer term problems such as chronic mental illness).

**Comment [tgs9]:** I think this is worth considering. We have the space to include a concise point about how situational factors can contribute to immediate risk.

**Comment [tgs9]:** I like this sentence.

**Comment [vid5]:** Similarly, wondering if we could condense this instead of reiterating some of these results and instead comment on the concept of

**Comment [tgs9]:** The reader won't know what you mean about norms here.

**Comment [vid5]:** I know we don't want to really be adding words – but I thought this is one thing that may not be obvious to everyone (why deaths of

**Comment [tgs9]:** I'm not sure that we need this. If we think it helps then I suggest that we shorten it and move it to the end to improve the flow. I added an

**Comment [tgs9]:** This was in the 2015 NVDRS SS. I think it would be good to include it here too. It will be good to confirm the accuracy with Katie.

**Comment [SD]:** Is it nationally representative at this point? Or no?

**Comment [vid5]:** Some suggested rephrasing here, because I don't want to trigger questions about why we would only use one data year of NVDRS data.

Third, abstractors of NVDRS data are limited to data included in the investigative reports they receive. For example, medical and mental health information are not captured directly from medical records but from informants (e.g., family, friends) via coroner/medical examiner reports and the decedent's family members and friends. Therefore, knowledge of the informant impacts completeness and accuracy of the information reported. This may explain some of the discrepancy between the prevalence of mental health disorders reported here (54%) and estimates from studies that estimate mental health problems based on symptoms described in interviews with family and friends. It is likely that some of those without known mental health problems were experiencing mental health challenges at the time of death, but the lack of awareness about their mental health problems underscores the importance of addressing the range of contributing circumstances. The 90% estimate is based on a limited number of studies.<sup>13</sup>

Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just one of many associated factors. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices*<sup>12</sup> and data from the [National Violent Death Reporting System NVDRS](#) can help states and communities prioritize comprehensive suicide prevention.

3 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

4 **Structured abstract (249/250 words)**

5 **Background:** Overall suicide rates have been rising in the United States (U.S.). Examining state-level trends in  
6 suicide and the multiple contributing circumstances can inform comprehensive state suicide prevention  
7 planning.

8 **Methods:** Trends in age-adjusted suicide rates, by state and sex, among people aged ≥10 years, were assessed  
9 using data from the National Vital Statistics System. Changes in rates were examined across six consecutive  
10 three-year periods from 1999-2016. The National Violent Death Reporting System (2015), covering 27 states,  
11 was used to ~~compare-examine~~ the precipitating circumstances ~~amongbetween~~ suicide decedents with and  
12 without known mental health problems (MHP).

13 **Results:** Forty-four states saw statistically significant suicide rate increases over the ~~study~~ period. In ~~30~~25 states,  
14 rates increased by ~~25%~~30% or more. Male suicide rates increased ~~significantly~~ in 34 states while female rates  
15 increased ~~significantly~~ in 43 states. People with (46%) and without (54%) known MHP had both differing and  
16 similar precipitating circumstances associated with their suicides. ~~Many-Several circumstancefactors~~, such as  
17 relationship problems (39.6 and 45.1%), life stressors (49.7 and 54.2%), and recent crises (26.0 and 32.9%),  
18 respectively, were more likely among those without known MHP, but were common among both groups.

19 **Conclusions:** Suicide rates rose significantly across most states from 1999-2016. ~~Varied circumstances beyond~~  
20 ~~MHP alone~~ contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a ~~comprehensive multi-level~~ public health approach  
22 based on the best available evidence to prevent ~~multiple~~ suicide risks before they occur, identify and support  
23 people already at risk, prevent-re-attempts, and help friends/family after a suicide occurs.

24 **INTRODUCTION**

25 **BACKGROUND AND PURPOSE (243/250 words)**

26 In 2016, nearly 45,000 suicides (~~13.4~~15.6/100,000) occurred in the United States (U.S.).<sup>1</sup> Between 1999 and  
27 2016, suicide rates increased among males and females, across racial/ethnic groups, and across urbanization  
28 levels.<sup>2,3</sup> Suicide is the 10<sup>th</sup> leading cause of death and is among the only leading causes to be ~~increasing~~.<sup>1,4</sup>  
29 Additionally, rates of Emergency Department visits for nonfatal self-harm injury, a key risk factor for suicide,  
30 increased more than 40% between 2001 and 2015.<sup>1</sup> Together, suicides and self-harm injuries cost the nation  
31 more than \$69 billion in direct medical and work loss costs.<sup>1</sup>

32 The National Strategy for Suicide Prevention<sup>5</sup> calls for a public health approach to suicide with prevention efforts  
33 reaching across the social ecology (i.e., individual, family/relationship, community, and societal levels). Such an  
34 approach highlights that suicide is rarely caused by any single factor but rather is multi-determined.<sup>5</sup> Despite  
35 this, suicide prevention efforts largely focus on identifying and treating high-risk individuals with mental illness.<sup>6</sup>  
36 However, other associated risk factors exist and include social and economic problems, access to lethal means  
37 (e.g. substances, firearms) among people at risk, poor coping and problem-solving skills, and prior suicide  
38 attempts, among others.<sup>5</sup> Expanded awareness of the multiple circumstances that contribute to suicide risk  
39 apart from mental health problems alone, can help ~~achieve substantial~~ reductions in suicide rates. To assist

**Comment [tgs9]:** Suggestion because we have not explained what we mean by multi-level yet. Also, we use “comprehensive” in the background so we can be consistent.

**Comment [snk6]:** It's 15.6 (age-adjusted) when using the population denominator ≥ 10 years of age. That's consistent with how we present rates elsewhere in this report (and with what we've already stated in the Abstract).

**Comment [snk6]:** Extra mark?

**Comment [tgs9]:** Edits to save words

states in reaching this goal through and toward comprehensive suicide prevention activities planning, this study analyzes state-specific trends in suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

#### **METHODS (246/250 words)**

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics among suicide decedents with and without known current mental health problems (MHP). MHP are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>7</sup> with the exception of alcohol and other substance dependence (captured separately). NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

#### **RESULTS (593/600 words)**

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least ~~25%~~30% observed in ever half of all states ~~(30)~~ as well as nationally.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for the overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known MHP were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

**Comment [vid5]:** Did we want to say why? This seems to always come up.

**Comment [snk6]:**  
Need to be careful here -- no longer true nationally with the newly adopted 30% threshold.

84 Although firearms were used most often in both groups, decedents with known MHP died by poisoning more  
85 than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs  
86 (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

87 All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had precipitating  
88 circumstances information. People with MHP were more likely to have any substance abuse problems (31.6% vs.  
89 25%,  $p < .01$ ). While two-thirds of those with known MHP had a history of MH or substance abuse treatment  
90 (67.2%), just over half (54.0%) were in current mental health treatment at the time of their deaths.

91 Decedents without known MHP had significantly greater odds of any type of relationship problem or loss (aOR =  
92 1.3, 95% CI = 1.2-1.4), specifically intimate partner problems (aOR = 1.4, 95% CI = 1.3-1.5), arguments/conflicts  
93 (aOR = 1.4, 95% CI = 1.3-1.5), and recently perpetrating interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4).  
94 They also had significantly greater odds of other life stressors, such as criminal legal problems (aOR = 1.7, 95% CI  
95 = 1.5-1.9) or eviction/loss of home (aOR = 1.4, 95% CI = 1.2-1.6), and they were also more likely to have had a  
96 crisis within the preceding or upcoming two weeks (aOR = 1.4, 95% CI = 1.3-1.5). Among both groups, the most  
97 common crises were intimate partner (35.6%) and physical health (13.4%) problems.

98 Decedents without known MHP had significantly lower odds of recent release from any institution, but when a  
99 release was indicated, they were more likely to be recently released from a correctional facility (aOR = 4.5, 95%  
100 CI = 3.2-6.3) or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently  
101 released from an institution (10.2%), 42.8% were released from psychiatric facilities.

102 Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95%  
103 CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p$   
104  $< .01$ ) and attempts (29.4% vs. 10.3%,  $p < .01$ ).

105 **Conclusions and Comments (698/700 words)**

106 From 1999-2016, 44 states saw significant rate increases. Half of the states experienced increases of 30% or  
107 more. Suicide rates increased by more than 25% in 30 states and upwards of 57% in one state, North Dakota.  
108 Rates increased significantly in 34 states among males and increased significantly in 43 states among females.  
109 More research into the causes of these trends is necessary.

110 One important factor associated with suicide is MHP. Nearly half of suicide decedents in NVDRS had a known  
111 MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicidal  
112 ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of MH and/or  
113 substance abuse treatment and over half were currently in treatment at the time of their deaths, additional  
114 support could help address the needs of this vulnerable population. This includes broader implementation of  
115 affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-  
116 behavioral therapy.<sup>8</sup> Additionally, greater access to behavioral health providers, especially in underserved areas  
117 is important, as is healthcare systems change that supports suicide prevention and patient safety through care  
118 transitions.<sup>8</sup>

119 While MHP are a significant contributor to suicide, 54% of suicide decedents in this study did not have a known  
120 MHP. This group suffered more relationship problems and life stressors such as criminal-legal matters,  
121 eviction/loss of home, and recent or impending crises. This is noteworthy in light of findings that suggest many  
122 suicides and attempts occur with minimal deliberation time, particularly among people without mental health  
123 disorders and who faced impending life crises.<sup>9,10</sup> People with known MHP also experienced other multiple life  
124 and other stressors such as job and/or financial problems, relationship problems, and physical health problems.

**Comment [tgs9]:** I'm wondering if we could add the %'s. This would make this consistent with the abstract and be more in line with our emphasis on the fact that there were differences but the circumstances are relevant for both groups.

The structure would stay the same. We could use the approach that you used below (green highlighted text) to make the % comparison and reflect the significance testing without giving the aOR and 95% CI's. This would also save words.

**Comment [snk6]:**

This sounds so precise all of a sudden, compared to the very general benchmark of 25% in this same sentence. I'm thinking about a different way to communicate this, but I don't have anything better at the moment.

**Comment [tgs9]:** I agree. What about taking out the ND point.

**Comment [tgs9]:** I think it would be good to cite some work that describes potential explanations and the need for additional research.

125 These findings point to the need to both prevent the conditions associated with mental health problems in the  
126 first place and the need to support people with MHP to decrease their vulnerability to poor social, health, and  
127 economic outcomes.<sup>11</sup>

128 These ~~underscore the importance of results point to the need for~~ comprehensive state suicide prevention  
129 ~~activities~~ that goes beyond a focus on MH treatment alone. Prevention strategies may include: strengthening  
130 economic supports (e.g. housing stabilization policies, household financial support), teaching coping and  
131 problem-solving skills, especially early in life to manage everyday stressors and prevent future relationship  
132 problems; and promoting social connectedness to increase a sense of belongingness and access to  
133 informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results  
134 include creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
135 organizational and workplace policies to promote help-seeking and positive social norms), supporting people  
136 after a suicide has taken place to ~~prevent survivors'~~ risk, and assuring safe reporting by the media in order to  
137 prevent suicide contagion.<sup>8</sup> ~~While few states have had the opportunity for such a comprehensive approach,~~  
138 ~~states such as Colorado are taking up the challenge.~~<sup>12</sup>

139 ~~These~~The study findings have at least three limitations. In four states (~~MD, UT, MA, RI~~ ~~MD, MA, RI, UT~~), rankings  
140 might have been impacted by large proportions of ~~injury~~ deaths of undetermined intent, or by decreased  
141 percentages of ~~undetermined-such~~ deaths over time, ~~which likely reflect include~~ some unrecognized suicides.  
142 Second, NVDRS is not yet nationally representative. This study used the most current data available ~~which and~~  
143 includes 27 states that represent half (49.6%) of the U.S. population. Third, abstractors of NVDRS data are  
144 limited to data included in investigative reports. For example, medical and MH information are not captured  
145 directly from medical records but from key informants (e.g., family, friends) via coroner/medical examiner  
146 reports. Therefore, knowledge of the informant impacts completeness and accuracy of the information  
147 reported, ~~and in-depth studies with family members often see greater attributions to mental health and~~  
148 ~~substance abuse disorders. This may explain some of the discrepancy between the prevalence of MHP reported~~  
149 ~~here and studies that obtain estimates based on in-depth interviews with next-of-kin.~~<sup>13</sup> It is likely that some  
150 people without known mental health problems in the current study were experiencing mental health challenges  
151 at the time of death, ~~that were either not known or reported by informants, or were not captured in reports~~  
152 ~~from NVDRS's primary data sources, but the absence of a diagnosis~~ underscores the importance of addressing  
153 ~~the range of other contributing circumstances.~~

154 Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is ~~just~~  
155 one of many. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and*  
156 *Practices*<sup>12</sup> and data from the NVDRS can help states and communities prioritize comprehensive suicide  
157 prevention.

4 **Structured abstract (249/250 words)**

5 **Background:** Overall suicide rates have been rising in the United States (U.S.). Examining state-level trends in  
6 suicide and the multiple contributing circumstances can inform comprehensive state suicide prevention  
7 planning.

8 **Methods:** Trends in age-adjusted suicide rates, by state and sex, among people aged ≥10 years, were assessed  
9 using data from the National Vital Statistics System. Changes in rates were examined across six consecutive  
10 three-year periods from 1999-2016. The National Violent Death Reporting System (2015), covering 27 states,  
11 was used to compare the precipitating circumstances between suicide decedents with and without known  
12 mental health problems (MHP).

13 **Results:** Forty-four states saw statistically significant suicide rate increases over the *study* period. In 30 states,  
14 rates increased by 25% or more. Male suicide rates increased *significantly* in 34 states while female rates  
15 increased *significantly* in 43. People with (46%) and without (54%) known MHP had both differing and similar  
16 precipitating circumstances associated with their suicides. Many factors, such as relationship problems (39.6  
17 and 45.1%), life stressors (49.7 and 54.2%), and recent crises (26.0 and 32.9%), respectively, were more likely  
18 among those without known MHP, but were common among both groups.

19 **Conclusions:** Suicide rates rose significantly across most states from 1999-2016. *Varied circumstances beyond*  
20 *MHP alone* contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a multi-level public health approach based on the best  
22 available evidence to prevent multiple suicide risks before they occur, identify and support people already at  
23 risk, prevent re-attempts, and help friends/family after a suicide occurs.

24 **INTRODUCTION**

25 **BACKGROUND AND PURPOSE (243/250 words)**

26 In 2016, nearly 45,000 suicides (*13.4*~~15.6~~/100,000) occurred in the United States (U.S.).<sup>1</sup> Between 1999 and  
27 2016, suicide rates increased among males and females, across racial/ethnic groups, and across urbanization  
28 levels.<sup>2,3</sup> Suicide is the 10<sup>th</sup> leading cause of death and is among the only leading causes to be *increasing*.<sup>1,4</sup>  
29 Additionally, rates of Emergency Department visits for nonfatal self-harm injury, a key risk factor for suicide,  
30 increased more than 40% between 2001 and 2015.<sup>1</sup> Together, suicides and self-harm injuries cost the nation  
31 more than \$69 billion in direct medical and work loss costs.<sup>1</sup>

32 The National Strategy for Suicide Prevention<sup>5</sup> calls for a public health approach to suicide with prevention efforts  
33 reaching across the social ecology (i.e., individual, family/relationship, community, and societal levels). Such an  
34 approach highlights that suicide is rarely caused by any single factor but rather is multi-determined.<sup>5</sup> Despite  
35 this, suicide prevention efforts largely focus on identifying and treating high-risk individuals with mental illness.<sup>6</sup>  
36 However, other associated risk factors exist and include social and economic problems, access to lethal means  
37 (e.g. substances, firearms) among people at risk, poor coping and problem-solving skills, and prior suicide  
38 attempts, among others.<sup>5</sup> Expanded awareness of the multiple circumstances that contribute to suicide risk  
39 apart from mental health problems alone, can help achieve substantial reductions in suicide rates. To assist

**Comment [snk6]:**

It's 15.6 (age-adjusted) when using the population denominator ≥ 10 years of age. That's consistent with how we present rates elsewhere in this report (and with what we've already stated in the Abstract).

states in this goal and toward comprehensive suicide prevention planning, this study analyzes state-specific trends in suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

## **METHODS (246/250 words)**

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics among suicide decedents with and without known current mental health problems (MHP). MHP are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>7</sup> with the exception of alcohol and other substance dependence (captured separately). NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## **RESULTS (593/600 words)**

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for the overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known MHP were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

84 Although firearms were used most often in both groups, decedents with known MHP died by poisoning more  
85 than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs  
86 (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

87 All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had precipitating  
88 circumstances information. People with MHP were more likely to have any substance abuse problems (31.6% vs.  
89 25%,  $p < .01$ ). While two-thirds had a history of MH or substance abuse treatment (67.2%), just over half (54.0%)  
90 were in current mental health treatment at the time of their deaths.

91 Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3,  
92 95% CI = 1.2-1.4), specifically intimate partner problems (aOR = 1.4, 95% CI = 1.3-1.5), arguments/conflicts (aOR  
93 = 1.4, 95% CI = 1.3-1.5), and recently perpetrating interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). They also  
94 had significantly greater odds of other life stressors, such as criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9)  
95 or eviction/loss of home (aOR = 1.4, 95% CI = 1.2-1.6), and they were also more likely to have a crisis within the  
96 preceding or upcoming two weeks (aOR = 1.4, 95% CI = 1.3-1.5). Among both groups, the most common crises  
97 were intimate partner (35.6%) and physical health (13.4%) problems.

98 Decedents without known MHP had significantly lower odds of recent release from any institution, but when a  
99 release was indicated, they were more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-  
100 6.3) or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released  
101 from an institution (10.2%), 42.8% were released from psychiatric facilities.

102 Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95%  
103 CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p$   
104  $\leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

#### 105 **Conclusions and Comments (698/700 words)**

106 From 1999-2016, 44 states saw significant rate increases. Suicide rates increased by more than 25% in 30 states  
107 and upwards of 57% in one state, North Dakota. Rates increased significantly in 34 states among males and  
108 increased significantly in 43 states among females. More research into the causes of these trends is necessary.

109 One important factor associated with suicide is MHP. Nearly half of suicide decedents in NVDRS had a known  
110 MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide  
111 ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of MH and/or  
112 substance abuse treatment and over half were currently in treatment at the time of their deaths, additional  
113 support could help address the needs of this vulnerable population. This includes broader implementation of  
114 affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-  
115 behavioral therapy.<sup>8</sup> Additionally, greater access to behavioral health providers, especially in underserved areas  
116 is important, as is healthcare systems change that supports suicide prevention and patient safety through care  
117 transitions.<sup>8</sup>

118 While MHP are a significant contributor to suicide, 54% of suicide decedents in this study did *not* have a known  
119 MHP. This group suffered more relationship problems and life stressors such as criminal-legal matters,  
120 eviction/loss of home, and recent or impending crises. This is noteworthy in light of findings that suggest many  
121 suicides and attempts occur with minimal deliberation time, particularly among people without mental health  
122 disorders and who faced impending life crises.<sup>9,10</sup> People with known MHP also experienced multiple life and  
123 other stressors such as job and/or financial problems, relationship problems, and physical health problems.

124 These findings point to the need to both prevent the conditions associated with mental health problems in the

#### **Comment [snk6]:**

This sounds so precise all of a sudden, compared to the very general benchmark of 25% in this same sentence. I'm thinking about a different way to communicate this, but I don't have anything better at the moment.

125 first place and the need to support people with MHP to decrease their vulnerability to poor social, health, and  
126 economic outcomes.<sup>11</sup>

127 These results point to the need for comprehensive state suicide prevention that goes beyond a focus on MH  
128 treatment alone. Prevention strategies may include: strengthening economic supports (e.g. housing stabilization  
129 policies, household financial support), teaching coping and problem-solving skills, especially early in life to  
130 manage everyday stressors and prevent future relationship problems; and promoting social connectedness to  
131 increase a sense of belongingness and access to informational, tangible, emotional, and social support, as  
132 needed. Other strategies indicated by these results include creating protective environments (e.g., reducing  
133 access to lethal means among people at risk, creating organizational and workplace policies to promote help-  
134 seeking and positive social norms), supporting people after a suicide has taken place to prevent survivors' risk,  
135 and assuring safe reporting by the media in order to prevent suicide contagion.<sup>8</sup> While few states have had the  
136 opportunity for such a comprehensive approach, states such as Colorado are taking up the challenge.<sup>12</sup>

137 ~~These~~ The study findings have at least three limitations. In four states (~~MD, UT, MA, RI~~ ~~(MD, MA, RI, UT)~~), rankings  
138 might have been impacted by large proportions of ~~injury~~ deaths of undetermined intent, or by decreased  
139 percentages of ~~undetermined-such~~ deaths over time, which likely ~~reflect-include~~ some unrecognized suicides.  
140 Second, NVDRS is not yet nationally representative. This study used the most current data available and  
141 includes 27 states that represent half (49.6%) of the U.S. population. Third, abstractors of NVDRS data are  
142 limited to data included in investigative reports. For example, medical and MH information are not captured  
143 directly from medical records but from key informants (e.g., family, friends) via coroner/medical examiner  
144 reports. Therefore, knowledge of the informant impacts completeness and accuracy of the information  
145 reported. This may explain some of the discrepancy between the prevalence of MHP reported here and studies  
146 that obtain estimates based on in-depth interviews with next-of-kin.<sup>13</sup> It is likely that some people without  
147 known mental health problems in the current study were experiencing mental health challenges at the time of  
148 death, but the absence of a diagnosis underscores the importance of addressing the range of other contributing  
149 circumstances.

150 Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just  
151 one of many. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and*  
152 *Practices*<sup>12</sup> and data from the NVDRS can help states and communities prioritize comprehensive suicide  
153 prevention.

4 **Structured abstract (249/250 words)**

5 **Background:** Overall suicide rates have been rising in the United States (U.S.). Examining state-level trends in  
6 suicide and the multiple contributing circumstances can inform comprehensive state suicide prevention  
7 planning.

8 **Methods:** Trends in age-adjusted suicide rates, by state and sex, among people aged  $\geq 10$  years, were assessed  
9 using data from the National Vital Statistics System. Changes in rates were examined across six consecutive  
10 three-year periods from 1999-2016. The National Violent Death Reporting System (2015), covering 27 states,  
11 was used to compare the precipitating circumstances between suicide decedents with and without known  
12 mental health problems (MHP).

13 **Results:** Forty-four states saw statistically significant suicide rate increases over the period. In 30 states, rates  
14 increased by 25% or more. Male suicide rates increased in 34 states while female rates increased in 43. People  
15 with (46%) and without (54%) known MHP had both differing and similar precipitating circumstances associated  
16 with their suicides. Many factors, such as relationship problems (39.6 and 45.1%), life stressors (49.7 and  
17 54.2%), and recent crises (26.0 and 32.9%), respectively, were more likely among those without known MHP,  
18 but were common among both groups.

19 **Conclusions:** Suicide rates rose significantly across most states from 1999-2016. Varied circumstances beyond  
20 MHP alone contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a multi-level public health approach based on the best  
22 available evidence to prevent multiple suicide risks before they occur, identify and support people already at  
23 risk, prevent-re-attempts, and help friends/family after a suicide occurs.

24 **INTRODUCTION**

25 **BACKGROUND AND PURPOSE (243/250 words)**

26 In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> Between 1999 and 2016,  
27 suicide rates increased among males and females, across racial/ethnic groups, and across urbanization levels.<sup>2,3</sup>  
28 Suicide, is the 10<sup>th</sup> leading cause of death and is among the only leading causes to be *increasing*.<sup>1,4</sup> Additionally,  
29 rates of Emergency Department visits for nonfatal self-harm injury, a key risk factor for suicide, increased more  
30 than 40% between 2001 and 2015.<sup>1</sup> Together, suicides and self-harm injuries cost the nation more than \$69  
31 billion in direct medical and work loss costs.<sup>1</sup>

32 The National Strategy for Suicide Prevention<sup>5</sup> calls for a public health approach to suicide with prevention efforts  
33 reaching across the social ecology (i.e., individual, family/relationship, community, and societal levels). Such an  
34 approach highlights that suicide is rarely caused by any single factor but rather is multi-determined.<sup>5</sup> Despite  
35 this, suicide prevention efforts largely focus on identifying and treating high-risk individuals with mental illness.<sup>6</sup>  
36 However, other associated risk factors exist and include social and economic problems, access to lethal means  
37 (e.g. substances, firearms) among people at risk, poor coping and problem-solving skills, and prior suicide  
38 attempts, among others.<sup>5</sup> Expanded awareness of the multiple circumstances that contribute to suicide risk  
39 apart from mental health problems alone, can help achieve substantial reductions in suicide rates. To assist

states in this goal and toward comprehensive suicide prevention planning, this study analyzes state-specific trends in suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

## **METHODS (246/250 words)**

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics among suicide decedents with and without known current mental health problems (MHP). MHP are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>7</sup> with the exception of alcohol and other substance dependence (captured separately). NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## **RESULTS (593/600 words)**

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known MHP were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

84 Although firearms were used most often in both groups, decedents with known MHP died by poisoning more  
85 than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs  
86 (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

87 All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had precipitating  
88 circumstances information. People with MHP were more likely to have any substance abuse problems (31.6% vs.  
89 25%,  $p < .01$ ). While two-thirds had a history of MH or substance abuse treatment (67.2%), just over half (54.0%)  
90 were in current mental health treatment at the time of their deaths.

91 Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3,  
92 95% CI = 1.2-1.4), specifically intimate partner problems (aOR = 1.4, 95% CI = 1.3-1.5), arguments/conflicts (aOR  
93 = 1.4, 95% CI = 1.3-1.5), and recently perpetrating interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). They also  
94 had significantly greater odds of other life stressors, such as criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9)  
95 or eviction/loss of home (aOR = 1.4, 95% CI = 1.2-1.6), and they were also more likely to have a crisis within the  
96 preceding or upcoming two weeks (aOR = 1.4, 95% CI = 1.3-1.5). Among both groups, the most common crises  
97 were intimate partner (35.6%) and physical health (13.4%) problems.

98 Decedents without known MHP had significantly lower odds of recent release from any institution, but when a  
99 release was indicated, they were more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-  
100 6.3) or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released  
101 from an institution (10.2%), 42.8% were released from psychiatric facilities.

102 Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95%  
103 CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p$   
104  $\leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

#### 105 **Conclusions and Comments (698/700 words)**

106 From 1999-2016, 44 states saw significant rate increases. Suicide rates increased by more than 25% in 30 states  
107 and upwards of 57% in one state, North Dakota. Rates increased in 34 states among males and increased in 43  
108 states among females. More research into the causes of these trends is necessary.

109 One important factor associated with suicide is MHP. Nearly half of suicide decedents in NVDRS had a known  
110 MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide  
111 ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of MH and/or  
112 substance abuse treatment and over half were currently in treatment at the time of their deaths, additional  
113 support could help address the needs of this vulnerable population. This includes broader implementation of  
114 affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-  
115 behavioral therapy.<sup>8</sup> Additionally, greater access to behavioral health providers, especially in underserved areas  
116 is important, as is healthcare systems change that supports suicide prevention and patient safety through care  
117 transitions.<sup>8</sup>

118 While MHP are a significant contributor to suicide, 54% of suicide decedents in this study did *not* have a known  
119 MHP. This group suffered more relationship problems and life stressors such as criminal-legal matters,  
120 eviction/loss of home, and recent or impending crises. This is noteworthy in light of findings that suggest many  
121 suicides and attempts occur with minimal deliberation time, particularly among people without mental health  
122 disorders and who faced impending life crises.<sup>9,10</sup> People with known MHP also experienced multiple life and  
123 other stressors such as job and/or financial problems, relationship problems, and physical health problems.  
124 These findings point to the need to both prevent the conditions associated with mental health problems in the

125 first place and the need to support people with MHP to decrease their vulnerability to poor social, health, and  
126 economic outcomes.<sup>11</sup>

127 These results point to the need for comprehensive state suicide prevention that goes beyond a focus on MH  
128 treatment alone. Prevention strategies may include: strengthening economic supports (e.g. housing stabilization  
129 policies, household financial support), teaching coping and problem-solving skills, especially early in life to  
130 manage everyday stressors and prevent future relationship problems; and promoting social connectedness to  
131 increase a sense of belongingness and access to informational, tangible, emotional, and social support, as  
132 needed. Other strategies indicated by these results include creating protective environments (e.g., reducing  
133 access to lethal means among people at risk, creating organizational and workplace policies to promote help-  
134 seeking and positive social norms), supporting people after a suicide has taken place to prevent survivors' risk,  
135 and assuring safe reporting by the media in order to prevent suicide contagion.<sup>8</sup> While few states have had the  
136 opportunity for such a comprehensive approach, states such as Colorado are taking up the challenge.<sup>12</sup>

137 These findings have at least three limitations. In four states (MD, UT, MA, RI), rankings might have been  
138 impacted by large proportions of deaths of undetermined intent, or by decreased percentages of undetermined  
139 deaths over time, which likely reflect some unrecognized suicides. Second, NVDRS is not yet nationally  
140 representative. This study used the most current data available and includes 27 states that represent half  
141 (49.6%) of the U.S. population. Third, abstractors of NVDRS data are limited to data included in investigative  
142 reports. For example, medical and MH information are not captured directly from medical records but from key  
143 informants (e.g., family, friends) via coroner/medical examiner reports. Therefore, knowledge of the informant  
144 impacts completeness and accuracy of the information reported. This may explain some of the discrepancy  
145 between the prevalence of MHP reported here and studies that obtain estimates based on in-depth interviews  
146 with next-of-kin.<sup>13</sup> It is likely that some people without known mental health problems in the current study were  
147 experiencing mental health challenges at the time of death, but the absence of a diagnosis underscores the  
148 importance of addressing the range of other contributing circumstances.

149 Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just  
150 one of many. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and*  
151 *Practices*<sup>12</sup> and data from the NVDRS can help states and communities prioritize comprehensive suicide  
152 prevention.

4 **Structured abstract (251/250 words)**

5 **Background:** Overall suicide rates have been rising in the United States. Examining state-level trends in suicide  
6 and its multiple contributing circumstances, can inform comprehensive state suicide prevention planning.

7 **Methods:** Trends in age-adjusted suicide rates, by state and sex, among people aged  $\geq 10$  years, were assessed  
8 using data from the National Vital Statistics System. Changes in rates were examined across six consecutive  
9 three-year periods from 1999-2016. The National Violent Death Reporting System (2015), covering 27 states,  
10 was used to examine the precipitating circumstances among suicide decedents with and without known mental  
11 health problems (MHP).

12 **Results:** Forty-four states saw statistically significant suicide rate increases from 1999-2016. In 25 states, rates  
13 increased by 30% or more. Male suicide rates increased significantly in 34 states while female rates increased  
14 significantly in 43 states. People with (46%) and without (54%) known MHP had both differing and similar  
15 circumstances precipitating suicide. Several circumstance, such as any relationship problems/loss (39.6 and  
16 45.1%,  $p \leq .01$ ), any life stressors/loss (49.7 and 54.2%,  $p \leq .01$ ), and recent crises (26.0 and 32.9%,  $p \leq .01$ ),  
17 respectively, were more likely among those without known MHP, but were common across groups.

18 **Conclusions:** Suicide rates rose significantly across most states from 1999-2016. Varied circumstances beyond  
19 MHP alone contributed to suicides among people with and without known MHP.

20 **Implications for Public Health Practice:** States can use a comprehensive public health approach based on the  
21 best available evidence to prevent suicide risks before they occur, identify and support people already at risk,  
22 prevent-re-attempts, and help friends/family after a suicide occurs.

23 **INTRODUCTION**

24 **BACKGROUND AND PURPOSE (260/250 words)**

25 In 2016, nearly 45,000 suicides (15.6/100,000) occurred in the United States (U.S.), among people  $\geq 10$  years [1].  
26 Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels [2,  
27 3]. Suicide is the 10<sup>th</sup> leading cause of death and is among the only leading causes to be *increasing* [1, 4].  
28 Additionally, rates of Emergency Department visits for nonfatal self-harm injury, a key risk factor for suicide,  
29 increased more than 40% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation  
30 more than \$69 billion in direct medical and work loss costs [1].

31 The *National Strategy for Suicide Prevention (NSSP)* [5] calls for a public health approach to suicide with  
32 prevention efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal ),  
33 of the social ecology. Such an approach underscores that suicide is rarely caused by any single factor alone, but  
34 rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on identifying  
35 and treating individuals with mental health problems (MHP) [6]. Other associated risk factors include social and  
36 economic problems, access to lethal means (e.g. substances, firearms, bridges) among people at risk, poor  
37 coping and problem-solving skills, and prior suicide attempts, among others [5]. Expanded awareness of the  
38 additional circumstances that contribute to suicide risk apart from MHP, can help reach the nation's goal of  
39 reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific

40 trends in suicide rates, assesses the multiple factors associated with suicide, and provides recommendations for  
41 multi-level comprehensive suicide prevention.

## 42 **METHODS (256/250 words)**

43 Suicide rate estimates and trend analyses exclude data for persons <10 years old because intent for self-harm  
44 typically is not attributed to young children. Age-specific suicide counts were tabulated based on National Vital  
45 Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10]  
46 underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from  
47 U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

48  
49 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
50 from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per  
51 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
52 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
53 are reported in terms of average annual percentage changes (AAPCs).

54  
55 Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting  
56 System (NVDRS) were used to compare the characteristics among suicide decedents with and without known  
57 current mental health problems (MHP). MHP are defined in NVDRS as disorders and syndromes listed in the  
58 *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* [8], except alcohol and other  
59 substance use disorders (captured separately). NVDRS aggregates data from three primary data sources: death  
60 certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents  
61 with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate  
62 adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## 63 **RESULTS (596/600 words)**

64 The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia) to 29.2  
65 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates  
66 increased in all but one state (Nevada), with absolute increases ranging from +0.2 (Delaware) to +8.1 (Wyoming)  
67 per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with  
68 percentage increases of at least 30% observed in half of all states.

69  
70 Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1).  
71 By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females.  
72 Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was  
73 +1.1% for males and +2.6% for females.

74  
75 Suicide decedents with (N=9,407) and without (N=11,039) known MHP were compared. While both groups were  
76 predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of  
77 being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic  
78 minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater  
79 odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR  
80 = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen  
81 percent of those with known MHP and 20% without ever served in the U.S. military.

82 Although firearms were used most often in both groups, decedents with known MHP died by poisoning more  
83 than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs  
84 (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

**Comment [zaf9]:** Realized this wasn't correct as stated. Did you guys notice I added this and is that how you'd (Katie) want to say it?

85 All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had precipitating  
86 circumstances information. People with MHP were more likely to have any substance abuse problems (31.6% vs.  
87 25%,  $p < .01$ ). While two-thirds of those with known MHP had a history of MH or substance abuse treatment  
88 (67.2%), just over half (54.0%) were in current mental health treatment at the time of their deaths.

89 Decedents without known MHP, ~~versus those with MHP~~ had ~~significantly greater odds of any type a greater~~  
90 ~~likelihood~~ of any relationship problem/-or-loss ((45.1 and 39.6%,  $p < .01$ , aOR = 1.3, 95% CI = 1.2-1.4), specifically  
91 intimate partner problems (30.2 and 24.1%,  $p < .01$ , aOR = 1.4, 95% CI = 1.3-1.5), arguments/conflicts (17.5 and  
92 13.6%,  $p < .01$ , aOR = 1.4, 95% CI = 1.3-1.5), and recently perpetrating interpersonal violence (3.0 and 1.4%,  $p < .01$ , aOR = 2.0, 95% CI = 1.6-2.4). They also had significantly greater odds of any other life stressors, such as  
93 criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9), 10.7 and 6.2%,  $p < .01$ ) or eviction/loss of home (aOR = 1.4,  
94 95% CI = 1.2-1.6), 4.3 and 3.4%,  $p < .01$ ), and they were also more likely to have had a crisis within the preceding or  
95 upcoming two weeks (32.9 and 26.0%,  $p < .01$ , aOR = 1.4, 95% CI = 1.3-1.5). Among both groups, the most  
96 common crises were intimate partner (35.6%) and physical health (13.4%) problems.

98 Decedents without known MHP had significantly lower odds of recent release from any institution, but when a  
99 release was indicated, they were more likely to be recently released from a correctional facility (aOR = 4.5, 95%  
100 CI = 3.2-6.3) or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP recently released from  
101 an institution (10.2%), 42.8% were released from psychiatric facilities.

102 Suicide decedents without known MHP ~~had significantly greater odds of were more likely to leave~~ a suicide  
103 note (35.1 and 31.8%,  $p < .01$ , aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP, compared to those  
104 without MHP, more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs.  
105 10.3%,  $p \leq .01$ ).

#### 106 Conclusions and Comments (688/700 words)

107 From 1999-2016, 44 states saw significant rate increases. Half of the states experienced increases of 30% or  
108 more. Rates increased significantly in 34 states among males and 43 states among females. More research into  
109 the causes of these trends is necessary [9].

110 One important factor associated with suicide is MHP. Nearly half of suicide decedents in NVDRS had a known  
111 MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicidal  
112 ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of MH and/or  
113 substance abuse treatment and over half were currently in treatment at the time of their deaths, additional  
114 support could help address the needs of this vulnerable population. This includes broader implementation of  
115 affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-  
116 behavioral therapy. Additionally, greater access to behavioral health providers, especially in underserved areas  
117 is important, as is healthcare systems change that supports suicide prevention and patient safety through care  
118 transitions [10].

119 While MHP are a significant contributor to suicide, 54% of suicide decedents in this study did *not* have a known  
120 MHP. This group suffered more relationship problems and life stressors such as criminal-legal matters,  
121 eviction/loss of home, and recent or impending crises. This is noteworthy in light of findings that suggest many  
122 suicides and attempts occur with minimal deliberation time, particularly among people without mental health  
123 disorders and who faced impending life crises [11, 12]. People with known MHP also experienced other life  
124 stressors such as job and/or financial problems, relationship problems, and physical health problems. These  
125 findings point to the need to both prevent the conditions associated with mental health problems in the first

Comment [zaf9]: I took Tom's suggestion and added the percentages instead of aORs. Not sure if this will be confusing now that some paragraphs are written one way (%) and others are written another (ORs).

Comment [zaf9]: This is a systematic review showing that socioeconomic factors are at least as important as MHP in suicide. Could instead link to something on the economy or the IOM report from 2002 which describes the many risk factors and the need to address them.

place and the need to support people with MHP to decrease their vulnerability to poor social, health, and economic outcomes [13].

These results underscore the importance of comprehensive state suicide prevention activities that go beyond a focus on MH treatment alone. Prevention strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills, especially early in life to manage everyday stressors and prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking and positive social norms), supporting family and friends after a suicide has taken place, and assuring safe reporting by the media in order to prevent suicide contagion [10]. Some states, such as Colorado, are underway planning and implementing a comprehensive approach to suicide prevention [14].

The study findings have at least three limitations. Related to state trend analyses, four states (MD, MA, RI, UT), rankings might have been impacted by large proportions of injury deaths of undetermined intent, or by decreased percentages of such deaths over time, which likely include some unrecognized suicides. Second, related to circumstances, NVDRS is not yet nationally representative. The most recent data from NVDRS inclusive of 27 states, represents half (49.6%) of the U.S. population. Third, NVDRS abstractors are limited to data from investigative reports. Health/mental health information is not captured directly from medical records but from key informants (e.g., family) via coroner/medical examiner reports. Therefore, completeness and accuracy of information is reliant on informant knowledge. Studies including in-depth interviews with key informants often see greater attributions to MH and substance abuse disorders [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges at the time of death that were either not known or reported by informants, or were not captured in NVDRS's primary data sources.

Suicide is a growing public health problem. Mental illness is an important risk factor for suicide, and is one of many requiring preventive action. Data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [10] can help states and communities better understand their suicide problem and prioritize comprehensive suicide prevention.

1 **Structured abstract (250/250 words)**

2 **Background:** Overall suicide rates have been rising in the United States (U.S.). Examining state-level trends in  
3 suicide and the multiple contributing circumstances can inform comprehensive state suicide prevention  
4 planning.

5 **Methods:** Trends in age-adjusted suicide rates, by state and sex, among people aged  $\geq 10$  years, were assessed  
6 using data from the National Vital Statistics System. Changes in rates and state rankings were examined across  
7 six consecutive three-year periods (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013, 2014-2016). The  
8 National Violent Death Reporting System (2015), covering 27 states, was used to compare the precipitating  
9 circumstances between suicide decedents with and without known mental health problems (MHP).

10 **Results:** Forty-four states saw statistically significant suicide rate increases, over the period. In 30 states, rates  
11 increased by 25% or more. Male suicide rates increased in 34 states while female rates increased in 43. People  
12 with (46%) and without (54%) known MHP had both unique and similar precipitating circumstances associated  
13 with their suicides, and many factors, such as relationship problems (39.6 and 45.1%), life stressors (49.7 and  
14 54.2%), and recent crises (26.0 and 32.9%), respectively, were common to both.

15 **Conclusions:** Suicide rates rose significantly across most states from 1999-2016. People with and without known  
16 MHP faced multiple circumstances contributing to their suicides.

17 **Implications for Public Health Practice:** To reverse upward suicide trends, states can use a multi-level public  
18 health approach based on the best available evidence to: prevent multiple suicide risks before they occurs,  
19 identify and support people already at risk, prevent-re-attempts, and help friends/family after a suicide occurs.

20 **INTRODUCTION**

21 **BACKGROUND AND PURPOSE (244/250 words) TOTAL COUNT=1757/1800**

22 In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> Between 1999 and 2016,  
23 suicide rates increased among males and females, across racial/ethnic groups, and across urbanization levels.<sup>3,4</sup>  
24 Suicide, is the 10<sup>th</sup> leading cause of death and is among the only leading causes to be *increasing*. Additionally,  
25 rates of Emergency Department visits for nonfatal self-harm injury, a key risk factor for suicide, increased more  
26 than 40% between 2001 and 2015.<sup>5</sup> Together, suicides and self-harm injuries cost the nation more than \$69  
27 billion in direct medical and work loss costs.<sup>1</sup>

28 The National Strategy for Suicide Prevention calls for a public health approach to suicide with prevention efforts  
29 reaching across the social ecology (i.e., individual, family/relationship, community, and societal levels). Such an  
30 approach highlights that suicide is rarely caused by any single factor but rather is multi-determined.<sup>6</sup> Despite  
31 this, suicide prevention efforts primarily focus on identifying and treating mental illness (e.g., depression).  
32 However, other associated risk factors exist and include social and economic problems, access to lethal means  
33 (e.g. substances, firearms) among people at risk, poor coping and problem-solving skills, and prior suicide  
34 attempts, among others.<sup>6</sup> Expanded awareness of the multiple circumstances that contribute to suicide risk  
35 apart from mental health problems alone, can help achieve substantial reductions in suicide rates. To assist  
36 states in this goal and toward comprehensive suicide prevention planning, this study analyzes state-specific  
37 trends in state suicide rates, assesses the multiple factors associated with suicide, and provides prevention  
38 recommendations.

39 **METHODS (246/250 words)**

Comment |SD(): Need to update

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03).<sup>8</sup> Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics among suicide decedents with and without known current mental health problems (MHP). MHP are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>9</sup> with the exception of alcohol and other substance dependence (captured separately). NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## **RESULTS (580/600 words)**

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known MHP were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

Although firearms were used most often in both groups, decedents with known MHP died by poisoning more than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had precipitating circumstances information. Two-thirds of decedents with known MHP had a history of MH or substance abuse treatment (67.2%) and were more likely to have any substance abuse problems (31.6% vs. 25%,  $p < .01$ ).

Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3, 95% CI = 1.2-1.4), specifically intimate partner problems (aOR = 1.4, 95% CI = 1.3-1.5), arguments/conflicts (aOR = 1.4, 95% CI = 1.3-1.5), and recently perpetrating interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). They also had significantly greater odds of other life stressors, such as criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9) or eviction/loss of home (aOR = 1.4, 95% CI = 1.2-1.6), and they were also more likely to have a crisis within the preceding or upcoming two weeks (aOR = 1.4, 95% CI = 1.3-1.5). Among both groups, the most common crises were intimate partner (35.6%) and physical health (13.4%) problems.

Decedents without known MHP had significantly lower odds of recent release from any institution, but when a release was indicated, they were more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-6.3) or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released from an institution (10.2%), 42.8% were released from psychiatric facilities.

Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

#### 100 Conclusions and Comments (684/700 words)

From 1999-2016, 44 states saw significant rate increases. One state (Nevada) saw a significant decline. Suicide rates increased by more than 25% in 30 states and upwards of 57% in one (North Dakota) state. Rates increased in 34 states among males and increased in 43 states among females. These increases may signal a narrowing of the suicide gender gap, historically weighted heavily towards males.<sup>11</sup> More research into this troubling trend is needed.

One important factor associated with suicide is MHP. Nearly half of suicide decedents in NVDRS had a known MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of MH and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, additional support could help address the needs of this vulnerable population. This includes broader implementation of affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral therapy.<sup>12</sup> Additionally, greater access to behavioral health providers, especially in underserved areas is important, as is healthcare systems change that supports suicide prevention and patient safety through care transitions.<sup>12</sup>

While MHP are a significant contributor to suicide, 54% of suicide decedents in this study did not have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence), but also related to other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the abovementioned factors). People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems, physical health problems, and recent or impending crises.

These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH treatment alone. Prevention strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills, especially early in life to manage everyday stressors and prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing

**Comment [HK]:** Can you say this? Wouldn't saying this imply that if IPP is checked as a precipitating factor, then relationship problems also has to be checked? Is that how NVDRS coding of IPP works? I thought these two categories were mutually exclusive in that IPP could be checked without relationship problems being checked.

This could be easily changed by just removing "specifically"

**Comment [vid5]:** Wondering if instead of recapping results, we could comment on the profound and not often discussed impact that life stressors, especially those that rise to the level of a crisis, can have. The research that shows the time amount of deliberation (which is often very low) may also be helpful to cite here, as these types of stressors/crises can represent short-term problems (vs. longer term problems such as chronic mental illness)

**Comment [tgs9]:** I think this is worth considering. We have the space to include a concise point about how situational factors can contribute to immediate risk and that some suicides are impulsive. This could probably be included at the end of the paragraph since it applies to both those with and without MH problem.

**Comment [vid5]:** Similarly, wondering if we could condense this instead of reiterating some of these results and instead comment on the concept of "functional impairment," as a reason why people with mental health problems might have more job/financial problems (e.g., they often have more inconsistent work histories as a result of trying to cope with their illness, perhaps have medical bills to deal with regarding treatment, periods of disability, etc.). This would go a little deeper and interpret the results a bit. I'm sure we could find some references on this.

128 access to lethal means among people at risk, creating organizational and workplace policies to promote help-  
129 seeking and positive social norms), supporting people after a suicide has taken place to prevent survivors' risk,  
130 and assuring safe reporting by the media in order to prevent suicide contagion.<sup>12</sup>

131 These findings have at least three limitations. In four states (MD, UT, MA, RI), rankings might have been  
132 impacted by large proportions of deaths of undetermined intent, or by decreased percentages of undetermined  
133 deaths over time, which likely reflect some unrecognized suicides. Second, NVDRS is not yet nationally  
134 representative. This study used the most current data available and includes 27 states that represent half  
135 (49.6%) of the U.S. (population). Third, abstractors of NVDRS data are limited to data included in investigative  
136 reports. For example, medical and MH information are not captured directly from medical records but from key  
137 informants (e.g., family, friends) via coroner/medical examiner reports. Therefore, knowledge of the informant  
138 impacts completeness and accuracy of the information reported. This may explain some of the discrepancy  
139 between the prevalence of mental health disorders reported here and that (from) studies that estimate mental  
140 health problems based on symptoms described in interviews with family and friends. It is likely that some people  
141 without known mental health problems in the current study were experiencing mental health challenges at the  
142 time of death, but the lack of awareness about their mental health problems underscores the importance of  
143 addressing the range of contributing circumstances.<sup>13</sup>

144 Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just  
145 one of many. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and*  
146 *Practices*<sup>12</sup> and data from the NVDRS can help states and communities prioritize comprehensive suicide  
147 prevention.

1 **Structured abstract (250/250 words)**

2 **Background:** Overall suicide rates have been rising in the United States (U.S.). Examining state-level trends in  
 3 suicide and the multiple contributing circumstances can inform comprehensive state suicide prevention  
 4 planning.

5 **Methods:** Trends in age-adjusted suicide rates, by state and sex, among people aged ≥10 years, were assessed  
 6 using data from the National Vital Statistics System. Changes in rates ~~and state rankings~~ were examined across  
 7 six consecutive three-year periods ~~from 1999-2016 (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013,~~  
 8 ~~2014-2016)~~. The National Violent Death Reporting System (2015), covering 27 states, was used to compare the  
 9 precipitating circumstances between suicide decedents with and without known mental health problems (MHP).

10 **Results:** Forty-four states saw statistically significant suicide rate increases, over the period. In 30 states, rates  
 11 increased by 25% or more. Male suicide rates increased in 34 states while female rates increased in 43. People  
 12 with (46%) and without (54%) known MHP had both differing and similar precipitating circumstances associated  
 13 with their suicides, and many factors, such as relationship problems (39.6 and 45.1%), life stressors (49.7 and  
 14 54.2%), and recent crises (26.0 and 32.9%), respectively, were more likely among those with no known MHP, but  
 15 were common among both groups.

16 ~~People with (46%) and without (54%) known MHP had both unique and similar precipitating circumstances~~  
 17 ~~associated with their suicides, and many factors, such as relationship problems (39.6 and 45.1%), life stressors~~  
 18 ~~(49.7 and 54.2%), and recent crises (26.0 and 32.9%), respectively, were common to both.~~

19 **Conclusions:** Suicide rates rose significantly across most states from 1999-2016. A variety of circumstances  
 20 beyond MHP contributed to suicides among P ~~People with and without known MHP faced multiple~~  
 21 ~~circumstances contributing to their suicides.~~

22 **Implications for Public Health Practice:** ~~To reverse upward suicide trends, s~~States can use a multi-level public  
 23 health approach based on the best available evidence to: prevent multiple suicide risks before they occurs,  
 24 identify and support people already at risk, prevent-reattempts, and help friends/family after a suicide occurs.

25 **INTRODUCTION**26 **BACKGROUND AND PURPOSE (244/250 words) TOTAL COUNT=1757/1800**

27 In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> Between 1999 and 2016,  
 28 suicide rates increased among males and females, across racial/ethnic groups, and across urbanization levels.<sup>3,4</sup>  
 29 Suicide, is the 10<sup>th</sup> leading cause of death and is among the only leading causes to be *increasing*. Additionally,  
 30 rates of Emergency Department visits for nonfatal self-harm injury, a key risk factor for suicide, increased more  
 31 than 40% between 2001 and 2015.<sup>5</sup> Together, suicides and self-harm injuries cost the nation more than ~~\$69~~  
 32 ~~billion~~ in direct medical and work loss costs.<sup>1</sup>

33 The National Strategy for Suicide Prevention calls for a public health approach to suicide with prevention efforts  
 34 reaching across the social ecology (i.e., individual, family/relationship, community, and societal levels). Such an  
 35 approach highlights that suicide is rarely caused by any single factor but rather is multi-determined.<sup>6</sup> Despite  
 36 this, suicide prevention efforts primarily focus on identifying and treating mental illness (e.g., depression).  
 37 However, other associated risk factors exist and include social and economic problems, access to lethal means  
 38 (e.g. substances, firearms) among people at risk, poor coping and problem-solving skills, and prior suicide  
 39 attempts, among others.<sup>6</sup> Expanded awareness of the multiple circumstances that contribute to suicide risk  
 40 apart from mental health problems alone, can help achieve substantial reductions in suicide rates. To assist

Comment [SD(): Need to update

states in this goal and toward comprehensive suicide prevention planning, this study analyzes state-specific trends in ~~state~~ suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

#### **METHODS (246/250 words)**

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03).<sup>8</sup> Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics among suicide decedents with and without known current mental health problems (MHP). MHP are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>9</sup> with the exception of alcohol and other substance dependence (captured separately). NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

#### **RESULTS (580/600 words)**

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia ~~(D.C.)~~) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known MHP were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

85 Although firearms were used most often in both groups, decedents with known MHP died by poisoning more  
 86 than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs  
 87 (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

88 All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had precipitating  
 89 circumstances information. Two-thirds of decedents with known MHP had a history of MH or substance abuse  
 90 treatment (67.2%) and were more likely to have any substance abuse problems (31.6% vs. 25%,  $p < .01$ ).

91 Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3,  
 92 95% CI = 1.2-1.4), specifically intimate partner problems (aOR = 1.4, 95% CI = 1.3-1.5), arguments/conflicts (aOR  
 93 = 1.4, 95% CI = 1.3-1.5), and recently perpetrating interpersonal violence (aOR = 2.0, 95% CI = 1.6-2.4). They also  
 94 had significantly greater odds of other life stressors, such as criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9)  
 95 or eviction/loss of home (aOR = 1.4, 95% CI 1.2-1.6), and they were also more likely to have a crisis within the  
 96 preceding or upcoming two weeks (aOR = 1.4, 95% CI = 1.3-1.5). Among both groups, the most common crises  
 97 were intimate partner (35.6%) and physical health (13.4%) problems.

98 Decedents without known MHP had significantly lower odds of recent release from any institution, but when a  
 99 release was indicated, they were more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-  
 100 6.3) or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released  
 101 from an institution (10.2%), 42.8% were released from psychiatric facilities.

102 Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95%  
 103 CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p$   
 104  $\leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

#### 105 **Conclusions and Comments (684/700 words)**

106 From 1999-2016, 44 states saw significant rate increases. ~~One state (Nevada) saw a significant decline.~~ Suicide  
 107 rates increased by more than 25% in 30 states and upwards of 57% in one (North Dakota) state. Rates increased  
 108 in 34 states among males and increased in 43 states among females. ~~These increases may signal a narrowing of~~  
 109 ~~the suicide gender gap, historically weighted heavily towards males.<sup>11</sup> More research into this troubling trend is~~  
 110 ~~needed.~~

111 One important factor associated with suicide is MHP. Nearly half of suicide decedents in NVDRS had a known  
 112 MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide  
 113 ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of MH and/or  
 114 substance abuse treatment and over half were currently in treatment at the time of their deaths, additional  
 115 support could help address the needs of this vulnerable population. This includes broader implementation of  
 116 affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-  
 117 behavioral therapy.<sup>12</sup> Additionally, greater access to behavioral health providers, especially in underserved areas  
 118 is important, as is healthcare systems change that supports suicide prevention and patient safety through care  
 119 transitions.<sup>12</sup>

120 While MHP are a significant contributor to suicide, 54% of suicide decedents in this study did *not* have a known  
 121 MHP. This group suffered more ~~life stressors, especially related to relationships (e.g. intimate partner problems,~~  
 122 ~~arguments or conflicts, -recent perpetration of intimate partner violence), but also related to other life stressors~~  
 123 ~~such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the~~  
 124 ~~abovementioned factors).~~ People with known MHP also experienced life and other stressors apart from their

**Comment [HK]:** Need to think about what to do with this sentence. – Perhaps delete and say “More research into these trends is needed.”

**Comment [vid5]:** Wondering if instead of recapping results, we could comment on the profound and not often discussed impact that life stressors, especially those that rise to the level of a crisis, can have. The research that shows the time amount of deliberation (which is often very low) may also be helpful to cite here, as these types of stressors/crises can represent short-term problems (vs. longer term problems such as chronic mental illness)

**Comment [tgs9]:** I think this is worth considering. We have the space to include a concise point about how situational factors can contribute to immediate risk and that some suicides are impulsive. This could probably be included at the end of the paragraph since it applies to both those with and without MH problem.

125 MHP. This group was more likely to experience job and/or financial problems. Also common were intimate  
126 partner problems, physical health problems, and recent or impending crises.)

127 These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH  
128 treatment alone. Prevention strategies may include: strengthening economic supports (e.g. housing stabilization  
129 policies, household financial support), teaching coping and problem-solving skills, especially early in life to  
130 manage everyday stressors and prevent future relationship problems; and promoting social connectedness to  
131 increase a sense of belongingness and access to informational, tangible, emotional, and social support, as  
132 needed. Other strategies indicated by these results include creating protective environments (e.g., reducing  
133 access to lethal means among people at risk, creating organizational and workplace policies to promote help-  
134 seeking and positive social norms), supporting people after a suicide has taken place to prevent survivors' risk,  
135 and assuring safe reporting by the media in order to prevent suicide contagion.<sup>12</sup>

136 These findings have at least three limitations. In four states (MD, UT, MA, RI), rankings might have been  
137 impacted by large proportions of deaths of undetermined intent, or by decreased percentages of undetermined  
138 deaths over time, which likely reflect some unrecognized suicides. Second, NVDRS is not yet nationally  
139 representative. This study used the most current data available and includes 27 states that represent half  
140 (49.6%) of the U.S. population. Third, abstractors of NVDRS data are limited to data included in investigative  
141 reports. For example, medical and MH information are not captured directly from medical records but from key  
142 informants (e.g., family, friends) via coroner/medical examiner reports. Therefore, knowledge of the informant  
143 impacts completeness and accuracy of the information reported. This may explain some of the discrepancy  
144 between the prevalence of mental health disorders reported here and that from studies that estimate mental  
145 health problems based on symptoms described in interviews with family and friends. It is likely that some people  
146 without known mental health problems in the current study were experiencing mental health challenges at the  
147 time of death, but the potential lack of awareness about their mental health problems underscores the  
148 importance of addressing the range of contributing circumstances.<sup>13</sup>

149 Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just  
150 one of many. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and*  
151 *Practices*<sup>12</sup> and data from the NVDRS can help states and communities prioritize comprehensive suicide  
152 prevention.

**Comment [vid5]:** Similarly, wondering if we could condense this instead of reiterating some of these results and instead comment on the concept of "functional impairment," as a reason why people with mental health problems might have more job/financial problems (e.g., they often have more inconsistent work histories as a result of trying to cope with their illness, perhaps have medical bills to deal with regarding treatment, periods of disability, etc.). This would go a little deeper and interpret the results a bit. I'm sure we could find some references on this.

**Comment [tgs9]:** This was in the 2015 NVDRS SS. I think it would be good to include it here too. It will be good to confirm the accuracy with Katie.

**Comment [tgs9]:** I agree with the comment below that including the 90% estimate here could be problematic. It might be better to describe the alternative types of studies. I suggested an edit so you can see what I mean but this will need to be updated to be consistent with what you cite.

#### Structured abstract (241/250 words)

**Background:** Suicide rates have been rising in the United States (U.S.). Examining state-level trends in, and contributing circumstances to, suicide, can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates, by ~~sex and state~~ **state and sex**, among people aged ≥10 years, were evaluated using data from the National Vital Statistics System. Changes in rates and state rankings were assessed across six consecutive three-year periods (1999-2001, 2002-2004, 2005-2007, 2008-2010, 2011-2013, 2014-2016). Data from 2015 from the National Violent Death Reporting System, across 27 states, were analyzed to compare precipitating circumstances between suicide decedents with and without known mental health problems.

**Results:** Statistically significant upward rate trends were identified for 44 states. For the U.S. overall and for 30 states individually, empirical rates increased by at least 25% over the study period. People with (46%) and without (54%) known mental health problems experienced a range of circumstances contributing to their suicides, including recent crises and problems related to substance use, relationships, job/financial issues, and criminal-legal matters.

**Conclusions:** Suicide rates have risen significantly in the U.S. and across most states from 1999-2016. No single factor alone contributes to suicide. Differing circumstances contribute to suicides among those with and without mental health problems.

**Implications for Public Health Practice:** To reverse upward trends in suicide, states can use a population-based public health approach inclusive of evidence-based strategies across multiple levels (individual, family/relationship, community, societal), focused on preventing risk before it starts, identifying and supporting people already at risk, preventing-re-attempts, and caring for survivors after a suicide.

#### INTRODUCTION

##### BACKGROUND AND PURPOSE (210/250 words) **TOTAL COUNT=1900/1800**

In 2016, nearly 45,000 suicides (13.4/100,000) occurred in the United States (U.S.).<sup>1</sup> While overall rates have been declining globally,<sup>2</sup> rates of suicide in the U.S. increased between 1999 and 2016, among males and females, across racial/ethnic groups, and across urbanization levels.<sup>3,4</sup> Emergency department visits for nonfatal self-harm injuries increased more than 40% between 2001 and 2015.<sup>5</sup> In 2015, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs.<sup>1</sup> Suicide is rarely caused by one factor; rather, the risks are often numerous and occur at multiple levels--individual, family/relationship, community, and societal.<sup>6</sup> Despite this, prevention primarily centers on mental illness, (e.g., depression, bipolar disorder). Other factors associated with suicide include social isolation, economic downturns, access to lethal means (e.g. substances, firearms) among people at risk, childhood adversity, lack of coping and problem-solving skills, loss of a friend or family member to suicide, a prior suicide attempt, and unsafe media portrayals, among others.<sup>6</sup> While the Surgeon General called for a comprehensive public health approach to suicide prevention in 1999, to date, most states struggle to make this a reality.<sup>7</sup> To better assist states, this study analyzes trends in state suicide rates, assesses the multiple factors associated with suicide, and provides prevention recommendations.

##### METHODS (259/250 words)

Suicide rate estimates and trend analyses exclude data for persons <10 years old. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of*

**Comment [snk6]:**

Really the more important ordering – my bad.

*Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, \*U03).<sup>8</sup> Age-specific population estimates were obtained from U.S. Census Bureau / National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods covering years 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting System (NVDRS) were used to compare the characteristics, including precipitating circumstances, of deaths by suicide among decedents with and without known current mental health problems (MHP). Mental health problems are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5),<sup>9</sup> with the exception of alcohol and other substance dependence (captured separately). NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (696/600 words)

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia [D.C.]) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with increases ranging from +0.2 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 25% observed in over half of all states (30), as well as nationally.

Modeled suicide rate trends ~~increased significantly indicate significant increases~~ for 44 states, as well as for the U.S. overall (Table 1). By sex, ~~modeled~~ rate trends ~~increased significantly indicate significant increases~~ in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for overall suicide rates was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known mental health problems (MHP) were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP had 2.3 greater odds of being male (95% confidence interval [CI] = 2.2-2.5), and significantly greater odds of being racial/ethnic minorities (odds ratio [OR] range: 1.0-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served in the U.S. military.

Although firearms were used most often in both groups, decedents with known MHP died by poisoning more than those without MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had known precipitating circumstances. Decedents without known MHP had significantly greater odds of any type of relationship problem (aOR = 1.3, 95% CI = 1.2-1.4), specifically intimate partner problems (aOR = 1.4, 95% CI = 1.3-1.5), arguments/conflicts (aOR = 1.4, 95% CI = 1.3-1.5), and recently perpetrating interpersonal violence

(aOR = 2.0, 95% CI = 1.6-2.4). Two-thirds of decedents with known MHP had a history of MH or substance abuse treatment (67.2%), and were more likely to have any substance abuse problems (31.6% vs. 25%,  $p \leq .01$ ),

Suicide decedents without known MHP had significantly greater odds of other life stressors, such as a criminal legal problems (aOR = 1.7, 95% CI = 1.5-1.9), or eviction/loss of home (aOR = 1.4, 95% CI 1.2-1.6). They had significantly lower odds of recent release from any institution, but when a release was indicated, they were significantly more likely to be released from a correctional facility (aOR = 4.5, 95% CI = 3.2-6.3), or hospital (aOR = 1.3, 95% CI = 1.1-1.7). Among decedents with known MHP who were recently released from an institution, 42.8% were from psychiatric institutions. Those with known MHP also more frequently had job and/or financial problems (16.8% vs. 15.6%;  $p \leq .05$ ).

Decedents without known MHP had significantly greater odds of a recent/impending crisis (aOR = 1.4, 95% CI = 1.3-1.5). When the type of crisis was known, it was most frequently related to an intimate partner (36.2%), physical health (13.8%), criminal legal issues (13.6%), family relationships (7.1%), or a job (5.3%). Over one-fourth of decedents with a known MHP also had recent or impending crises, most frequently related to an intimate partner (34.9%), physical health (12.9%), or family relationships (8.7%). Decedents without known MHP had significantly greater odds of criminal legal crises (aOR = 1.6, 95% CI = 1.3-1.9), and significantly lowered odds of job-related crises (aOR = 0.7, 95% CI = 0.5-0.8).

Suicide decedents without known MHP had significantly greater odds of leaving a suicide note (aOR = 1.2, 95% CI = 1.1-1.2), while decedents with known MHP more often had a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

### **Conclusions and Comments (735/700 words)**

From 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall. Forty-four states saw significant rate increases and one (Nevada) state saw a significant decline. Suicide rates increased by more than 25% in 30 states and upwards of 50% in some.

Among females, rates increased in 43 states and rates among males increased in 34. This signal of increasing vulnerability of females towards suicide aligns with recent reports that identified a 63% increase in middle-aged female suicide rates between 1999-2014 and an annual increase of 18.8% per year in emergency department visits for self-inflicted injuries among young females, aged of 10 and 14, in the period 2009-2015.<sup>3,10</sup> These increases may hint at a narrowing of the suicide gender gap, historically weighted towards males by a ratio of 4-5:1.<sup>11</sup> More research into this troubling trend is needed.

One important factor associated with suicide is mental health problems. Nearly half of people in this study had a known mental health problem. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicide ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of mental health and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, much more support for this vulnerable population is needed. This includes the need for broader implementation of affordable and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral therapy.<sup>12</sup> Additionally, greater access to behavioral health providers, especially in underserved areas is needed, as is healthcare systems change that supports suicide prevention and patient safety.<sup>12</sup>

While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did *not* have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence), but also related to other

life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises (often related to the abovementioned factors). People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%).

These results point to the need for comprehensive suicide prevention that goes beyond a focus on MH treatment alone. These strategies may include: strengthening economic supports (e.g. housing stabilization policies, household financial support), teaching coping and problem-solving skills and other pro-social norms, especially early in life to manage everyday stressors and to prevent future relationship problems; and promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, as needed. Other strategies indicated by these results include creating protective environments (e.g., reducing access to lethal means among people at risk, and creating organizational and workplace policies to promote help-seeking and positive social norms), and supporting people after a suicide has taken place to prevent survivors' risk and to assure safe reporting by the media in order to prevent suicide contagion.<sup>12</sup>

These findings have at least three limitations. In four states, Maryland (MD), Utah (UT), Massachusetts (MA), and Rhode Island (RI), state rankings might have been impacted by large proportions of deaths of undetermined intent (MD), which often represent cases where a suicide determination was judged not to be conclusive, or by decreased percentages of undetermined deaths over time (UT, MA, RI). Second, NVDRS is not yet nationally representative. Currently, 40 states, the District of Columbia, and Puerto Rico participate in NVDRS, but the most recent available data year includes 27 states as others joined the system later. Third, abstractors of NVDRS data are limited to data included in investigative reports. For example, medical and mental health information are not captured directly from medical records but from informants (e.g., family, friends) via coroner/medical examiner reports. Therefore, knowledge of the informant impacts completeness and accuracy of the information reported. This may explain some of the discrepancy between the prevalence of mental health disorders reported here (54%) and the 90% statistic frequently cited in other studies.<sup>13</sup>

Suicide is a growing public health problem and mental illness is an important risk factor for suicide, but is just one of many associated factors. Resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices*<sup>12</sup> and the National Violent Death Reporting System can help states and communities prioritize comprehensive suicide prevention.

### From Katie:

I went through the latest draft w/Alex's comments, comparing the results and discussion. Most lined up, although there were a few places where I noticed some mismatch ("" is from the draft, bold are my comments):

"From 1999-2016, age-adjusted suicide rates among people  $\geq 10$  years increased 25.4% overall." **We give the national (overall) number only in the abstract, not in the results.**

"Suicide rates increased by more than 25% in 30 states and upwards of 50% in some". **We only mention one (North Dakota) that is over 50% in the results (rather than "some").**

"While two-thirds of people with MHP had a history of mental health and/or substance abuse treatment and over half were currently in treatment at the time of their deaths, much more support for this vulnerable population is needed." **The highlighted point is only in the table right now– could add to results text.**

"While MHP are a significant contributor to suicide, 54% of suicide decedents in the current study did *not* have a known MHP. This group suffered more life stressors, especially related to relationships (e.g. intimate partner problems, arguments or conflicts, recent perpetration of intimate partner violence)..." **Didn't notice this the first time around, but the highlighted portion should read "recent perpetration of interpersonal violence" – that variable is not specific to IPV.**

"People with known MHP also experienced life and other stressors apart from their MHP. This group was more likely to experience job and/or financial problems. Also common were intimate partner problems (24.1%), physical health problems (21.4%), and recent or impending crises (26%)." **The numbers in the highlighted portion are in the table, but not specifically cited in the results (because we report odds ratios instead).**

2 **Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

3  
4 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
5 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

6  
7 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP)  
8 are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing  
9 circumstances to, suicide can inform comprehensive state suicide prevention planning.

10  
11 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
12 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
13 for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states  
14 in 2015, were used to examine contributing circumstances among decedents with and without known mental  
15 health problems (MHP).

16  
17 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
18 of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In  
19 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with  
20 circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life  
21 stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among  
22 those without a known MHP than decedents with MHP, but were common across groups.

23  
24 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
25 contributed to suicides among people with and without known MHP.

26  
27 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
28 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
29 friends/family after a suicide occurs.

30  
31 **INTRODUCTION**

32  
33 **BACKGROUND AND PURPOSE**

34  
35 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
36 ≥10 years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and  
37 urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
38 are *increasing* (1, 4). Additionally, rates of emergency department visits for nonfatal self-harm, a key risk factor  
39 for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the  
40 nation more than \$69 billion in direct medical and work loss costs (1).

41  
42 The *National Strategy for Suicide Prevention(NSSP)* (5) calls for a public health approach to suicide prevention  
43 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such a  
44 comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is multi-  
45 determined. Despite the NSSP guidance, suicide prevention largely focuses on identifying suicidal people,  
46 providing treatment for mental health problems (MHP) and preventing re-attempts (6). In addition to MHP and  
47 prior attempts, other contributing circumstances to suicide include social and economic problems, access to  
48 lethal means (e.g., substances, firearms) among people at risk, and poor coping and problem-solving skills (5).  
49 Expanded awareness of these additional circumstances contributing to suicide risk and action to address them,

4.25.18

can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides options for multi-level comprehensive suicide prevention based on the best available evidence.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8).

1 4.25.18

2 Among adult decedents, 20.1% of those without known MHP and 15.3% of those with MPH ever served, or were  
3 currently serving, in the U.S. military.

4 While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents  
5 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
6 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
7 These differences remained significant in the adjusted models.

8 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
9 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
10 CI=0.7-0.8), such as opioids (aOR=.90 95% CI=0.81-.99) but more likely to test positive for alcohol (aOR=1.2, 95%  
11 CI=1.1-1.3).

12 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
13 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
14 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
15 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

16 Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship  
17 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
18 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely  
19 to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or  
20 eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or  
21 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
22 Among all people with crises, intimate partner problems were the most common types and did not differ by  
23 group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and  
24 job/financial problems (15.6% and 16.8%) were commonly experienced by both groups.

25 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
26 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
27 released from a correctional facility (25.7% vs. 8.7%), hospital (43.7% vs. 33.0%), or other facility (e.g.,  
28 alcohol/substance treatment) (aOR=2.5 95% CI=1.8-3.3), than those with a known MHP. Among decedents with  
29 known MHP who were recently released from an institution (10.2%), 46.7% of this group were released from  
30 psychiatric facilities.

31 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
32 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
33 both groups disclosed suicide intent (22.4% vs. 24.5%).

34 **Conclusions and Comments**

35 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
36 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
37 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
38 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
39 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
40 circumstances and can help states identify prevention priorities.

4.25.18

Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention is often oriented towards downstream identification of suicidal people, treatment of MHP and prevention of reattempts. Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as the current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more from relationship problems and other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.

Similarly, people with MHP often experienced relationship problems and other life stressors such as job/financial and/or physical health problems. These findings point to the need to both help people manage the conditions associated with mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known MHP suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

<sup>§</sup> Odds ratio reflects the risk among those without known mental health problem relative to those with known MHP.

<sup>¶</sup> Logistic regression was used to estimate adjusted odds ratio with 95% CIs after controlling for age, sex, race and ethnicity. Known MHP was used as the reference group.

<sup>\*\*</sup> Decedents were aged 10 years and older, as per standard in the suicide prevention literature.

<sup>††</sup> Denominator is decedents aged 18 years of age and older with reported military service status.

<sup>§§</sup> Denominator is decedents who died by poisoning, including overdose.

<sup>¶¶</sup> Denominator is decedents with any toxicology tested.

<sup>\*\*\*</sup> Denominator for each positive group is the number tested for the substance in that group.

MMWR Author Submission Checklist

Proprietary Considerations	
<input checked="" type="checkbox"/>	Authors acknowledge that if their report is accepted for publication in the <a href="#">Morbidity and Mortality Weekly Report (MMWR)</a> , CDC will commit the report to the public domain and will allow its contents to be used and reprinted without permission. Citation as to source, however, is appreciated.
<input checked="" type="checkbox"/>	To the extent allowed by law, authors agree that they have obtained all appropriate written permissions to allow the submitted report to be published by the United States Government in <i>MMWR</i> and committed to the public domain. This includes written permission from publishers of any copyrighted text boxes, figures or tables that will be reprinted or adapted in an <i>MMWR</i> report.
<input checked="" type="checkbox"/>	Authors agree to obtain appropriate written permissions from any persons identifiable in photographs, case descriptions, or pedigrees for the use of their information and/or image in the report to be published and committed to the public domain.
<input checked="" type="checkbox"/>	Authors agree to obtain appropriate written permissions from persons named in personal communications (oral or written), stating that they agree to be named in the report to be published and committed to the public domain and that the information cited is accurate and (as applicable) retrievable. Such written permissions should be uploaded to <i>MMWR</i> ScholarOne Manuscripts as part of the report submission.
<input checked="" type="checkbox"/>	This report (or one with substantially similar content written by the authors) has not been published and is not being considered for publication elsewhere.
<input checked="" type="checkbox"/>	The <a href="#">Instructions for Authors</a> for <i>MMWR</i> Weekly have been carefully reviewed, with particular attention to Clearance requirements. For reports with CDC authors, <a href="#">Evidence of Clearance</a> has been included with submission. For reports with only non-CDC authors, <i>MMWR</i> will facilitate and confirm clearance by the appropriate CDC center(s) before publication.
<input checked="" type="checkbox"/>	Non-CDC authors have advised the state epidemiologist or the Ministry of Health, as appropriate, of their submission.
<input checked="" type="checkbox"/>	The <a href="#">International Committee of Medical Journal Editors (ICMJE) Conflict of Interest Form</a> has been completed for each author and uploaded to <i>MMWR</i> ScholarOne Manuscripts as part of the submission. All potential conflicts of interest described in the ICMJE form are disclosed in the report's Acknowledgments.
<input checked="" type="checkbox"/>	Authors have disclosed all funding, other financial and material support, and the funder's role (e.g., development of report, analysis and involvement in the publication process) in the report's Acknowledgments.
<input checked="" type="checkbox"/>	Corresponding author is the primary contact for approving the report prior to publication, as well as reviewing, and responding to the comments in the edited drafts and proofs provided by <i>MMWR</i> editors, and responding to CDC Media Relations.

<input checked="" type="checkbox"/>	If errata are identified after publication, the corresponding author will notify <i>MMWR</i> and provide cleared content for publication in a timely manner.
<input checked="" type="checkbox"/>	Corresponding author has ensured that all authors have identified and addressed ethical considerations (e.g., IRB review, disclosure of conflicts, reporting of relevant financial considerations, and review of report to identify possible research misconduct). In general, <i>MMWR</i> follows guidance from the Committee on Publication Ethics (COPE), <a href="#">Guidelines on Good Publication Practice</a> and ICMJE's <a href="#">Recommendations for the Conduct, Reporting, Editing, and Publication of Scholarly work in Medical Journals</a> . If you have any questions about ethical considerations or reporting disclosures (conflicts of interest or funding sources/ funder role), please contact the Executive Editor prior to submitting your report.
<b>Authorship and Acknowledgments</b>	
<input checked="" type="checkbox"/>	All authors and contributors meet criteria for <a href="#">CDC Authorship Policy</a> and guidance from <a href="#">ICMJE</a> , and all persons who made substantial contributions to this work but who did not fulfill the authorship criteria are named in the Acknowledgments. <i>MMWR</i> follows <a href="#">U.S. National Library of Medicine</a> guidance for designating authorship and other contributions in MEDLINE.
<input checked="" type="checkbox"/>	Written permission has been obtained and archived from all persons listed in the Acknowledgments that they agree to be named in the report to be published and committed to the public domain.
<input checked="" type="checkbox"/>	Written permission has been obtained and archived from all persons listed as authors of this report that they agree to be named in the report to be published and committed to the public domain.
<input checked="" type="checkbox"/>	All author contact information is up-to-date in <i>MMWR</i> ScholarOne Manuscripts.
<b>Formatting, References, Figures, Word Count, Units of Measure</b>	
<input checked="" type="checkbox"/>	If authors have previously discussed the proposed report with the <i>MMWR</i> editors, this is described in the cover letter.
<input checked="" type="checkbox"/>	Authors have complied with guidance provided in the <a href="#">Instructions for Authors</a> .
<input checked="" type="checkbox"/>	Authors have reviewed recent <a href="#">MMWR Weekly reports</a> on the same or similar topics for basic format and styles.
<input checked="" type="checkbox"/>	The report meets specified word count for the type of report submitted, or the rationale to exceed the word count is provided in the cover letter.
<input checked="" type="checkbox"/>	All pages are double-spaced, numbered, and left justified (ragged right margin).
<input checked="" type="checkbox"/>	All references are cited in the text in sequential order, comply with <a href="#">ICMJE Uniform Requirements</a> , and have been checked for accuracy and completeness. Reference "callouts" in text must be indicated by an italic number in parentheses. Number of references do not exceed the maximum for the type of submission.
	Ex.: "Advances in water management and sanitation have substantially reduced waterborne disease in the United States, although outbreaks continue to occur (1)."

<input checked="" type="checkbox"/>	<p>Author names have been provided in the format shown in the following example. Only the highest academic degrees (not certifications) have been listed, at the master's level or higher. When an author has two degrees at the same level (e.g., MD, PhD, or MS, MPH) both have been listed. Degrees have been followed by a superscripted numeral corresponding to the affiliation. Numerals are listed in sequential order.</p> <p>Ex.: "Karlyn D. Beer, PhD<sup>1,2</sup>; Julia W. Gargano, PhD<sup>2</sup>; Preeta K. Kutty, MD<sup>3</sup>; Elizabeth D. Hilborn, DVM<sup>4</sup>; Jonathan S. Yoder, MPH, MSW<sup>2</sup>"</p>
<input checked="" type="checkbox"/>	<p>Affiliations for authors have been provided in the format shown in the following example. No more than two affiliation sublevels (e.g., division, center) have been listed. The corresponding author is listed in the appropriate location and format.</p> <p>Ex.: "<sup>1</sup>Epidemic Intelligence Service, CDC; <sup>2</sup>Division of Foodborne, Waterborne, and Environmental Diseases, National Center for Emerging and Zoonotic Infectious Diseases, CDC; <sup>3</sup>Division of Bacterial Diseases, National Center for Immunization and Respiratory Diseases, CDC; <sup>4</sup>U.S. Environmental Protection Agency. Corresponding author: Karlyn Beer, kbeer@cdc.gov, 404-718-1151."</p>
<input checked="" type="checkbox"/>	<p>Footnote "callouts" have been indicated in the text with the correct sequential symbols. Footnotes are grouped as "plain text" endnotes beneath the references in the submission. No reference manager or footnote/endnote programs or Word features are included in the submission.</p>
<input checked="" type="checkbox"/>	<p>Tables have been submitted in the formats described in the <a href="#">Instructions for Authors</a>. Tables should be sent in separate files and not embedded in the text.</p>
<input checked="" type="checkbox"/>	<p>In tables, confidence intervals have been headed with (95% CI), and parentheses also placed around each value in the column. Footnote symbols are placed sequentially in the table, beginning with the title and then moving from left to right, row by row in the table.</p>
<input checked="" type="checkbox"/>	<p>Each table and figure has a "complete" title, such that a reader can have a general understanding of what the data represent without reading the text.</p> <p>Ex.: "TABLE 1. Waterborne disease outbreaks associated with drinking water (N = 32), by state/jurisdiction and month of first case onset — Waterborne Disease and Outbreak Surveillance System, United States, 2011–2012"</p>
<input checked="" type="checkbox"/>	<p>Figures have been submitted in the formats described in the <a href="#">Instructions for Authors</a>. Maps have been submitted in one of the proper editable formats.</p>
<input checked="" type="checkbox"/>	<p>For figures, all footnote symbols have been placed in the title. New process requirements do not permit placement of footnote symbols within figures</p>
<input checked="" type="checkbox"/>	<p>The number of figures, tables, and/or boxes included with submission do not exceed the maximum number for the type of submission.</p>

**Vital Signs: ~~Contributing Circumstances to Suicide and Increasing~~ Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015**

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999, ~~and m-~~ Mental health problems ~~(MHP)~~ are just one factor contributing to suicide. Examining state-level trends in, and the multiple ~~contributing~~ circumstances ~~contributing~~ to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and ~~the District of Columbia (DC) Washington, D.C.~~ Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems ~~(MHP)~~.

**Results:** ~~From During~~ 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known ~~MHP~~ mental health problem. Among persons with circumstance information, several circumstances ~~were significantly more likely among those without a known mental health problems than among decedents with mental health problems~~, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) ~~were~~

4.25.18

~~significantly more likely among those without a known MHP than decedents with MHP~~, but ~~these~~  
~~circumstances~~ were common across groups.

**Conclusions:** Suicide rates increased significantly across most states ~~from during~~ 1999–2016.

Various circumstances contributed to suicides among persons with and without known ~~MHP~~mental  
health problems.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public  
health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent  
re-attempts, and help friends/family after a suicide occurs.

INTRODUCTION

BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United  
States ~~(U.S.)~~, among persons aged ≥10 years ~~old~~ (1). Between 1999 and 2015, suicide rates increased  
~~among both across~~ sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide is the 10<sup>th</sup>  
leading cause of death and is one of just three leading causes that are increasing (1,4). Additionally,  
rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased  
nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation  
more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention* (NSSP) (5) calls for a public health approach to suicide  
prevention with efforts spanning ~~across~~ multiple levels (i.e., individual, family/relationship,  
community, and societal). Such a comprehensive approach underscores that suicide is rarely caused  
by any single factor, but rather, is determined by multiple factors ~~determined~~. Despite the NSSP  
guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for  
mental health problems ~~(MHP)~~ and preventing re-attempts (6). In addition to ~~MHP~~mental health

4.25.18

problems and prior attempts, other contributing circumstances contributing to suicide include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzed CDC analyzed state-specific trends in suicide rates, assessed the multiple contributing factors to suicide, and presents options for multi-level comprehensive suicide prevention based on the best available evidence.

## METHODS

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999–2016 (1999–2001, 2002–2004, 2005–2007, 2008–2010, 2011–2013, and 2014–2016). Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

4.25.18

Characteristics and circumstances of ~~suicide decedents~~persons aged  $\geq 10$  years who died by suicide ~~old~~, with and without known ~~MHP~~mental health problems, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines ~~MHP~~mental health problems as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known ~~MHP~~mental health problems were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

RESULTS

The most recent overall suicide rates (representing 2014–2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 ~~per 100,000~~ (Delaware) to +8.1 (Wyoming) ~~per 100,000~~. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1) ~~(, Figure 1)~~.

Modeled suicide rate trends indicated significant increases ~~for in~~ 44 states, ~~for among~~ males (34 states) and females (43 states), as well as for the ~~United States~~ overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known ~~MHP~~mental health problems ( $N=11,039$ ) were compared ~~to~~ with those with known mental health problems ( $N=9,407$ ) in 27 states. ~~Whereas~~ all

**Comment [GJ(1):** Suggest including this table in CDC Stacks with a link; it is 7 pages long and too long for an MMWR report. That would change your current table 2 to table 1 and your current table 3 to table 2.

4.25.18

decedents were predominately male (76.8%) (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known ~~MHP~~mental health problems, relative to those with ~~MHP~~mental health problems, were more likely male (83.6% ~~versus~~ 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and racial/ethnic minorities (OR range: 1.2–2.0). Suicide decedents without known ~~MHP~~mental health problems also had significantly ~~greater~~ higher odds of perpetrating homicide-suicide (adjusted odds ratio (aOR) = 2.9, 95% CI = 2.2–3.8). Among adult decedents, 20.1% of those without known ~~MHP~~mental health problems and 15.3% of those with ~~MHP~~mental health problems had ever served, or were currently serving, in the U.S. military.

Comment [GJ(2): ?aged ≥18 years?]

~~While-Whereas~~ firearms were the most common method of suicide ~~used~~ overall (48.5%) and for decedents with and without mental health problems ~~both groups~~, decedents without known ~~MHP~~mental health problems were more likely to die by firearm (55.3% ~~versus~~ 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% ~~versus~~ 31.3%) or poisoning (10.4% ~~versus~~ 19.8%) than ~~were~~ those with known ~~MHP~~mental health problems. These differences remained significant in the adjusted models.

Decedents without known ~~MHP~~mental health problems were less likely to receive toxicology testing. Among those with toxicology results, decedents without known ~~MHP~~mental health problems were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), ~~such as including~~ opioids (aOR = 0.90 95% CI = 0.81–0.99), but ~~were~~ more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

~~Information on circumstances surrounding suicide were available for a-~~All suicide decedents with ~~MHP~~mental health problems (N = 9,407) and approximately 85% of those without known ~~MHP~~mental health problems (N = 9,357) ~~had available circumstances information~~ (Table 3).

Persons without known ~~MHP~~mental health problems were less likely to have any substance abuse

4.25.18

problems (aOR= 0.7, 95% CI= 0.7–0.8). Whereas two thirds of those decedents with known MHPmental health problems had a history of mental health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without, versus those with, known MHPmental health problems, had a significantly greater-higher likelihood of any relationship problem/loss (45.1%) than did those with known mental healthproblems (-vs- 39.6%), specifically intimate partner problems (30.2% versus: 24.1%), arguments/conflicts (17.5% versus: 13.6%), and recently perpetrating interpersonal violence (3.0% versus: 1.4%). Decedents without known mental health problems They also were also more likely than those without known mental health problems to have experienced any life stressors (54.2% versus 49.7%); such as criminal-legal problems (10.7% versus: 6.2%); or eviction/loss of home (4.3% versus: 3.4%) and were more likely to have had a crisis within the preceding or upcoming two weeks (32.9% versus: 26.0%). All of these differences remained significant in the adjusted models.

Among all persons with recent crises, intimate partner problems were the most common types and did not differ by group. Similarly, physical health problems and job/financial problems were commonly experienced among both persons without versus with MHPmental health problems (23.2% and 15.6%, respectively) and those with mental health problems, physical health problems (23.2% and 21.4%) and job/financial problems (15.6% and and -16.8%, respectively) were commonly experienced by both groups.

Decedents without known MHPmental health problems had significantly lower odds of recent release from any institution (aOR= 0.5, 95% CI= 0.4–0.5), but among those who were recently released (5.1%), they were significantly more likely to have been released from a correctional facility (25.7% vs-versus 8.7%), hospital (43.7% vs-versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR= 2.5 95% CI= 1.8–3.3), than those with a known MHPmental health

Comment [GJ(3)]: How is this defined?

Comment [GJ(4)]: Unclear what this means, if they were already dead. Do you mean an impending crisis?

4.25.18

problems. Among decedents with known MHPmental health problems who were recently released from an institution (10.2%), 46.7% of this group were released from psychiatric facilities.

Decedents without known MHPmental health problems; compared to those with MHP, were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health problems (-vs. 40.8% and 29.4%, respectively) and prior suicide attempts (10.3% vs. 29.4%). Suicide intent was disclosed by 22.4% and 24.5% of More than one in five persons without and with known mental health problems, respectively in both groups disclosed suicide intent (22.4% vs. 24.5%).

#### Conclusions and Comments

From During 1999–2016, suicide rates increased significantly in 44 states, and saw significant increases in suicide rates and 25 states experienced substantial increases in suicide rates of more than 30%. Rates increased significantly among males; in 34 states, and females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-female suicide rates between during 1999–2014 (3). Additional research into the specific causes of these trends is necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into circumstances surrounding suicide circumstances and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor; (5); however, suicide prevention is often oriented towards downstream identification of suicidal persons, treatment of MHPmental health problems and prevention of reattempts. This study found that more than half of suicide decedents in NVDRS did not have a known mental health problems, indicating that aAdditional focus on non-mental health factors, further upstream, is essential to a public health approach (10); as the current study found that more than half of suicide decedents in NVDRS did

4.25.18

~~not have a known MHP~~. This group suffered more from relationship problems and other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with ~~MHP~~mental health problems often experienced relationship problems and other life stressors such as job/financial and/or physical health problems. These findings point to the need to both help persons manage the conditions associated with mental health problems in the first place, and to support persons with known ~~MHP~~mental health problems to decrease their risk of poor outcomes (11). Two thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies.

Additionally, ~~greater~~increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems ~~needed~~ that integrates physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging~~ness~~ and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., ~~military v~~veterans, persons with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with ~~MHP~~mental health problems and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent

Formatted: Font: Not Italic

4.25.18

suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

Formatted: Font: Italic

The ~~se~~ findings in this report are subject to ~~have~~ at least three limitations. In the state-level analysis, rankings for four states (~~Maryland, Massachusetts, Rhode Island, and Utah~~, MA, RI, UT) might have been ~~impacted-affected~~ by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population

(<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

~~Third~~Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can ~~impact-affect~~ data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often ~~see-identify~~ greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known ~~MHP~~mental health problems in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known ~~MHP~~mental health problems suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

**Comment [GJ(5)]:** Vital Signs reports now require a summary box like other MMWR full reports. The summary should address, in 100 words or less (not counting headings), the following 3 questions:

1. What is already known about this topic?
2. What is added by this report?
3. What are the implications for public health practice?

TABLE 2. Select demographic and descriptive characteristics of suicides aged ≥10 years with and without known mental health problems — National Violent Death Reporting System, 27 states,\* 2015

Abbreviation: CI = confidence interval.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

<sup>§</sup> Odds ratio reflects the risk among those without known mental health problem relative to those with known mental health problem.

<sup>¶</sup> Logistic regression was used to estimate adjusted odds ratio with 95% CIs after controlling for age, sex, race and ethnicity. Known mental health problem was used as the reference group.

<sup>\*\*</sup> Decedents were aged  $\geq 10$  years, as per standard in the suicide prevention literature.

<sup>††</sup> Denominator is decedents aged  $\geq 18$  years with reported military service status.

<sup>§§</sup> Denominator is decedents who died by poisoning, including overdose.

<sup>¶¶</sup> Denominator is decedents with any toxicology tested.

<sup>\*\*\*</sup> Denominator for each positive group is the number tested for the substance in that group.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

† Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

‡ Odds ratio reflects the risk among those without known mental health problem relative to those with known mental health problem.

§ Logistic regression was used to estimate adjusted odds ratio with 95% CIs after controlling for age, sex, race and ethnicity. Known mental health problem was the reference group.

¶ Includes decedents with one or more diagnosed current mental health problems, which are not mutually exclusive. Therefore, sums of percentages for the diagnosed conditions exceed 100%. Denominator includes the number of decedents with one or more current diagnosed mental health problems.

†† Denominator is decedents aged ≥18 years.

§§ Denominator is decedents aged 10–18 years.

¶ Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

\*\*\* Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

## Morbidity and Mortality Weekly Report

### Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Journal:	<i>Morbidity and Mortality Weekly Report</i>

**Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six consecutive three-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999–2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

**INTRODUCTION**

**BACKGROUND AND PURPOSE**

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people ≥10 years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention largely focuses on identifying suicidal people, providing treatment for mental health problems (MHP) and preventing re-attempts (6). In addition to MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them,

4.25.18

can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides options for multi-level comprehensive suicide prevention based on the best available evidence.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8).

4.25.18

Among adult decedents, 20.1% of those without known MHP and 15.3% of those with MPH ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP. These differences remained significant in the adjusted models.

Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95% CI=0.7-0.8), such as opioids (aOR=.90 95% CI=0.81-.99) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available circumstances information (Table 3). People without known MHP were less likely to have any substance abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models. Among all people with crises, intimate partner problems were the most common types and did not differ by group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and job/financial problems (15.6% and 16.8%) were commonly experienced by both groups.

Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5, 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be released from a correctional facility (25.7% vs. 8.7%), hospital (43.7% vs. 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR=2.5 95% CI=1.8-3.3), than those with a known MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this group were released from psychiatric facilities.

Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in both groups disclosed suicide intent (22.4% vs. 24.5%).

Conclusions and Comments

From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide circumstances and can help states identify prevention priorities.

4.25.18

Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention is often oriented towards downstream identification of suicidal people, treatment of MHP and prevention of reattempts. Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as the current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more from relationship problems and other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.

Similarly, people with MHP often experienced relationship problems and other life stressors such as job/financial and/or physical health problems. These findings point to the need to both help people manage the conditions associated with mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known MHP suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

<sup>§</sup> Odds ratio reflects the risk among those without known mental health problem relative to those with known MHP.

<sup>¶</sup> Logistic regression was used to estimate adjusted odds ratio with 95% CIs after controlling for age, sex, race and ethnicity. Known MHP was used as the reference group.

<sup>\*\*</sup> Decedents were aged 10 years and older, as per standard in the suicide prevention literature.

<sup>††</sup> Denominator is decedents aged 18 years of age and older with reported military service status.

<sup>§§</sup> Denominator is decedents who died by poisoning, including overdose.

<sup>¶¶</sup> Denominator is decedents with any toxicology tested.

<sup>\*\*\*</sup> Denominator for each positive group is the number tested for the substance in that group.

---

\*Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

<sup>§</sup> Odds ratio reflects the risk among those without known mental health problem relative to those with known MHP.

<sup>¶</sup> Logistic regression was used to estimate adjusted odds ratio with 95% CIs after controlling for age, sex, race and ethnicity. Known MHP was used as the reference group.

<sup>\*\*</sup> Includes decedents with one or more diagnosed current mental health problems, which are not mutually exclusive. Therefore sums of percentages for the diagnosed conditions exceed 100%. Denominator includes the number of decedents with one or more current diagnosed mental health problems.

<sup>††</sup> Denominator is decedents aged 18 years of age and older.

<sup>§§</sup> Denominator is decedents aged 10-18 years.

<sup>\*\*</sup> Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

<sup>\*\*\*</sup> Denominator of crisis subgroup is decedents with any crisis within past or upcoming two weeks. Crises depicted here represent the most commonly occurring categories.

MMWR Author Submission Checklist

Proprietary Considerations	
<input checked="" type="checkbox"/>	Authors acknowledge that if their report is accepted for publication in the <a href="#">Morbidity and Mortality Weekly Report (MMWR)</a> , CDC will commit the report to the public domain and will allow its contents to be used and reprinted without permission. Citation as to source, however, is appreciated.
<input checked="" type="checkbox"/>	To the extent allowed by law, authors agree that they have obtained all appropriate written permissions to allow the submitted report to be published by the United States Government in <i>MMWR</i> and committed to the public domain. This includes written permission from publishers of any copyrighted text boxes, figures or tables that will be reprinted or adapted in an <i>MMWR</i> report.
<input checked="" type="checkbox"/>	Authors agree to obtain appropriate written permissions from any persons identifiable in photographs, case descriptions, or pedigrees for the use of their information and/or image in the report to be published and committed to the public domain.
<input checked="" type="checkbox"/>	Authors agree to obtain appropriate written permissions from persons named in personal communications (oral or written), stating that they agree to be named in the report to be published and committed to the public domain and that the information cited is accurate and (as applicable) retrievable. Such written permissions should be uploaded to <i>MMWR</i> ScholarOne Manuscripts as part of the report submission.
<input checked="" type="checkbox"/>	This report (or one with substantially similar content written by the authors) has not been published and is not being considered for publication elsewhere.
<input checked="" type="checkbox"/>	The <a href="#">Instructions for Authors</a> for <i>MMWR</i> Weekly have been carefully reviewed, with particular attention to Clearance requirements. For reports with CDC authors, <a href="#">Evidence of Clearance</a> has been included with submission. For reports with only non-CDC authors, <i>MMWR</i> will facilitate and confirm clearance by the appropriate CDC center(s) before publication.
<input checked="" type="checkbox"/>	Non-CDC authors have advised the state epidemiologist or the Ministry of Health, as appropriate, of their submission.
<input checked="" type="checkbox"/>	The <a href="#">International Committee of Medical Journal Editors (ICMJE) Conflict of Interest Form</a> has been completed for each author and uploaded to <i>MMWR</i> ScholarOne Manuscripts as part of the submission. All potential conflicts of interest described in the ICMJE form are disclosed in the report's Acknowledgments.
<input checked="" type="checkbox"/>	Authors have disclosed all funding, other financial and material support, and the funder's role (e.g., development of report, analysis and involvement in the publication process) in the report's Acknowledgments.
<input checked="" type="checkbox"/>	Corresponding author is the primary contact for approving the report prior to publication, as well as reviewing, and responding to the comments in the edited drafts and proofs provided by <i>MMWR</i> editors, and responding to CDC Media Relations.

<input checked="" type="checkbox"/>	If errata are identified after publication, the corresponding author will notify <i>MMWR</i> and provide cleared content for publication in a timely manner.
<input checked="" type="checkbox"/>	Corresponding author has ensured that all authors have identified and addressed ethical considerations (e.g., IRB review, disclosure of conflicts, reporting of relevant financial considerations, and review of report to identify possible research misconduct). In general, <i>MMWR</i> follows guidance from the Committee on Publication Ethics (COPE), <a href="#">Guidelines on Good Publication Practice</a> and ICMJE's <a href="#">Recommendations for the Conduct, Reporting, Editing, and Publication of Scholarly work in Medical Journals</a> . If you have any questions about ethical considerations or reporting disclosures (conflicts of interest or funding sources/ funder role), please contact the Executive Editor prior to submitting your report.
<b>Authorship and Acknowledgments</b>	
<input checked="" type="checkbox"/>	All authors and contributors meet criteria for <a href="#">CDC Authorship Policy</a> and guidance from <a href="#">ICMJE</a> , and all persons who made substantial contributions to this work but who did not fulfill the authorship criteria are named in the Acknowledgments. <i>MMWR</i> follows <a href="#">U.S. National Library of Medicine</a> guidance for designating authorship and other contributions in MEDLINE.
<input checked="" type="checkbox"/>	Written permission has been obtained and archived from all persons listed in the Acknowledgments that they agree to be named in the report to be published and committed to the public domain.
<input checked="" type="checkbox"/>	Written permission has been obtained and archived from all persons listed as authors of this report that they agree to be named in the report to be published and committed to the public domain.
<input checked="" type="checkbox"/>	All author contact information is up-to-date in <i>MMWR</i> ScholarOne Manuscripts.
<b>Formatting, References, Figures, Word Count, Units of Measure</b>	
<input checked="" type="checkbox"/>	If authors have previously discussed the proposed report with the <i>MMWR</i> editors, this is described in the cover letter.
<input checked="" type="checkbox"/>	Authors have complied with guidance provided in the <a href="#">Instructions for Authors</a> .
<input checked="" type="checkbox"/>	Authors have reviewed recent <a href="#">MMWR Weekly reports</a> on the same or similar topics for basic format and styles.
<input checked="" type="checkbox"/>	The report meets specified word count for the type of report submitted, or the rationale to exceed the word count is provided in the cover letter.
<input checked="" type="checkbox"/>	All pages are double-spaced, numbered, and left justified (ragged right margin).
<input checked="" type="checkbox"/>	All references are cited in the text in sequential order, comply with <a href="#">ICMJE Uniform Requirements</a> , and have been checked for accuracy and completeness. Reference "callouts" in text must be indicated by an italic number in parentheses. Number of references do not exceed the maximum for the type of submission.
	Ex.: "Advances in water management and sanitation have substantially reduced waterborne disease in the United States, although outbreaks continue to occur (1)."

<input checked="" type="checkbox"/>	<p>Author names have been provided in the format shown in the following example. Only the highest academic degrees (not certifications) have been listed, at the master's level or higher. When an author has two degrees at the same level (e.g., MD, PhD, or MS, MPH) both have been listed. Degrees have been followed by a superscripted numeral corresponding to the affiliation. Numerals are listed in sequential order.</p> <p>Ex.: "Karlyn D. Beer, PhD<sup>1,2</sup>; Julia W. Gargano, PhD<sup>2</sup>; Preeta K. Kutty, MD<sup>3</sup>; Elizabeth D. Hilborn, DVM<sup>4</sup>; Jonathan S. Yoder, MPH, MSW<sup>2</sup>"</p>
<input checked="" type="checkbox"/>	<p>Affiliations for authors have been provided in the format shown in the following example. No more than two affiliation sublevels (e.g., division, center) have been listed. The corresponding author is listed in the appropriate location and format.</p> <p>Ex.: "<sup>1</sup>Epidemic Intelligence Service, CDC; <sup>2</sup>Division of Foodborne, Waterborne, and Environmental Diseases, National Center for Emerging and Zoonotic Infectious Diseases, CDC; <sup>3</sup>Division of Bacterial Diseases, National Center for Immunization and Respiratory Diseases, CDC; <sup>4</sup>U.S. Environmental Protection Agency. Corresponding author: Karlyn Beer, kbeer@cdc.gov, 404-718-1151."</p>
<input checked="" type="checkbox"/>	<p>Footnote "callouts" have been indicated in the text with the correct sequential symbols. Footnotes are grouped as "plain text" endnotes beneath the references in the submission. No reference manager or footnote/endnote programs or Word features are included in the submission.</p>
<input checked="" type="checkbox"/>	<p>Tables have been submitted in the formats described in the <a href="#">Instructions for Authors</a>. Tables should be sent in separate files and not embedded in the text.</p>
<input checked="" type="checkbox"/>	<p>In tables, confidence intervals have been headed with (95% CI), and parentheses also placed around each value in the column. Footnote symbols are placed sequentially in the table, beginning with the title and then moving from left to right, row by row in the table.</p>

## Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

### Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are one of several factors contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition.

Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health conditions, including relationship problems/loss (45.1% versus 39.6%), life stressors (50.5% versus 47.2%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanized areas (2,3). Suicide rates have also increased among persons in all age groups  $< 75$  years, with adults aged 45–64 having the largest percent increase (45%; from 13.2 per 100,000 persons [1999] to 19.2 per 100,000 [2016]) and the greatest number of suicides (32,108 from 1999 to 2016) (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$70 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on mental health conditions alone by identifying suicidal persons, providing treatment for mental health conditions, and preventing reattempts (6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances

include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for strategies to include in comprehensive suicide prevention efforts that are based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years because determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007;

Could not make your change as written. We avoid using qualifiers such as just, only, considerably, particularly, which are often based on opinions.

Is this correct as written, that they had the largest increase? If not, can we just say having an increase of 45%?

Also, could not find this reported in tables. Is this a "data not shown" situation, in which case we should probably say that (Division or branch or program, data not shown, 201X).

 Author: zaf9      Subject: Sticky Note      Date: 5/30/2018 11:23:26 AM  
It's not correct to say that group has the largest increase but it has 'one of the largest percent increases and the greatest number of suicides.' This is not part of our analysis which is why it's not in the table. I think the references cited should suffice, no?

per year

2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

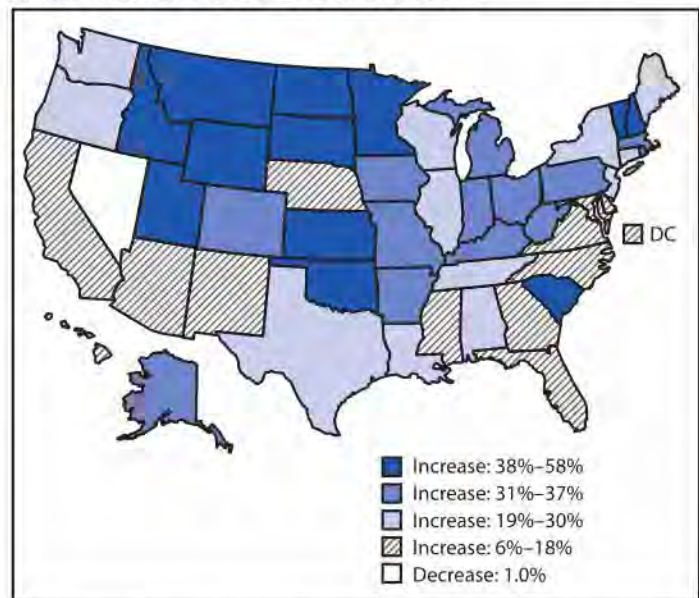

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of problematic alcohol and other substance use that is captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent or impending crises) have been identified as potential risk factors for suicide. Circumstances captured by NVDRS are those identified as contributing to suicide in coroner/medical examiner or law enforcement reports, which reflect information provided by family and friends. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using  $\chi^2$ -square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table;

**FIGURE. Percent change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016**

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

<https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall suicide rate was an increase of 15%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (13%) and females (14%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (12,039; 10%) were compared with those with known mental health conditions (91,507; 13%) in 14 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio [OR] = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide followed by suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had ever served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%), decedents without known mental health conditions were more likely to die by firearm (55.3%) and less likely to die by hanging/strangulation/suffocation (26.9%) or poisoning (10.4%) than were those with known mental health conditions (40.6%, 31.3%, and 19.8%, respectively). These differences remained significant in the adjusted models.

See table footnotes on next page.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions (n = 9,407) and approximately 85% of those without known mental health conditions (n = 9,357) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any problematic substance use (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and perpetrating interpersonal violence in the past month (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (50.5% versus 47.2%) such as criminal legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job/financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and

**Abbreviations:** CI = confidence interval; NA = not adjusted; NS = not significant; OR = odds ratio.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

† Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely than decedents with mental health problems to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility, such as an alcohol/substance use treatment facility (24.2% versus 11.6%). Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation

(23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often

oriented toward mental health conditions alone with regard to downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions also often experienced other factors, such as relationship problems and other life stressors such as job/financial or physical health problems that contributed to their suicide. These findings point to the need to both prevent the circumstances associated with the onset of mental health conditions in the first place and support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for mental health or substance use disorders, with approximately half in treatment when they died. This finding suggests the

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

<sup>§</sup> OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

<sup>¶</sup> Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health condition was the reference group.

<sup>\*\*</sup> Includes decedents with one or more diagnosed current mental health conditions, which are not mutually exclusive. Therefore, sums of percentages for the diagnosed conditions exceed 100%. Denominator includes the number of decedents with one or more current diagnosed mental health conditions.

<sup>††</sup> Decedents with no known mental health conditions do not have mental health conditions; therefore total values are equal to the known mental health condition values.

<sup>§§</sup> Not a diagnosis.

<sup>¶¶</sup> Denominator is decedents aged  $\geq 18$  years.

<sup>\*\*\*</sup> Denominator is decedents aged 10–18 years.

<sup>†††</sup> Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

<sup>§§§</sup> Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk for suicide, creating organizational and workplace policies to promote help-seeking, easing transitions

into and out of work for persons with mental health conditions and other life challenges), strengthening access and delivery of care, supporting family and friends after a suicide, and assuring the media follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations

## References

## Summary

## What is already known about this topic?

In 2016, nearly 45,000 persons died by suicide in the United States. Mental health conditions are one of several contributors to suicide.

## What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. <sup>1</sup>Other contributors included <sup>2</sup>relationship, substance use, health, and job or financial problems, <sup>3,4</sup>among others, <sup>5,6</sup>

## What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

across studies exist (14). It is likely that some persons without known mental health conditions in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NCHS and resources such as CDC's Preventing Suicide: A Technical Package of Policy, Programs, and Practices (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people ≥10 years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention largely focuses on identifying suicidal people, providing treatment for mental health problems (MHP) and preventing re-attempts (6). In addition to MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal,

this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides options for multi-level comprehensive suicide prevention based on the best available evidence.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% of those without known MHP and 15.3% of those with MPH ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
85 These differences remained significant in the adjusted models.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8), such as opioids (aOR=.90 95% CI=0.81-.99) but more likely to test positive for alcohol (aOR=1.2, 95%  
89 CI=1.1-1.3).

90 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
91 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
92 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
93 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

94 Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship  
95 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
96 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely  
97 to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or  
98 eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or  
99 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
100 Among all people with crises, intimate partner problems were the most common types and did not differ by  
101 group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and  
102 job/financial problems (15.6% and 16.8%) were commonly experienced by both groups.

103 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
104 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
105 released from a correctional facility (25.7% vs. 8.7%), hospital (43.7% vs. 33.0%), or other facility (e.g.,  
106 alcohol/substance treatment) (aOR=2.5 95% CI=1.8-3.3), than those with a known MHP. Among decedents with  
107 known MHP who were recently released from an institution (10.2%), 46.7% of this group were released from  
108 psychiatric facilities.

109 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
110 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
111 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 112 **Conclusions and Comments**

113 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
114 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
115 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
116 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
117 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
118 circumstances and can help states identify prevention priorities.

119 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention is often  
120 oriented towards downstream identification of suicidal people, treatment of MHP and prevention of reattempts.  
121 Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as  
122 the current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This  
123 group suffered more from relationship problems and other life stressors such as criminal-legal matters,  
124 eviction/loss of home, and recent or impending crises.

Similarly, people with MHP often experienced relationship problems and other life stressors such as job/financial and/or physical health problems. These findings point to the need to both help people manage the conditions associated with mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population

(<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known MHP suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

# **Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## **INTRODUCTION**

### **BACKGROUND AND PURPOSE**

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people ≥10 years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention largely focuses on identifying suicidal people, providing treatment for mental health problems (MHP) and preventing re-attempts (6). In addition to MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them,

can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides options for multi-level comprehensive suicide prevention based on the best available evidence.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8).

Among adult decedents, 20.1% of those without known MHP and 15.3% of those with MPH ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP. These differences remained significant in the adjusted models.

Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95% CI=0.7-0.8), such as opioids (aOR=.90 95% CI=0.81-.99) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available circumstances information (Table 3). People without known MHP were less likely to have any substance abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models. Among all people with crises, intimate partner problems were the most common types and did not differ by group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and job/financial problems (15.6% and 16.8%) were commonly experienced by both groups.

Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5, 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be released from a correctional facility (25.7% vs. 8.7%), hospital (43.7% vs. 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR=2.5 95% CI=1.8-3.3), than those with a known MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this group were released from psychiatric facilities.

Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in both groups disclosed suicide intent (22.4% vs. 24.5%).

### **Conclusions and Comments**

From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide circumstances and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention is often oriented towards downstream identification of suicidal people, treatment of MHP and prevention of reattempts. Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as the current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more from relationship problems and other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.

Similarly, people with MHP often experienced relationship problems and other life stressors such as job/financial and/or physical health problems. These findings point to the need to both help people manage the conditions associated with mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population

(<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known MHP suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

## **Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015**

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

### **Abstract**

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are one of several factors contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition.

Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health conditions, including relationship problems/loss (45.1% versus 39.6%), life stressors (50.5% versus 47.2%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among persons in all age groups  $< 75$  years, with adults aged 45–64 having the largest absolute rate increase (from 13.2 per 100,000 persons [1999] to 19.2 per 100,000 [2016]) and the greatest number of suicides (232,108) during the same period (1,3). Suicide is the tenth leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$70 billion per year in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite this call to action, suicide prevention largely focuses on identifying and referring suicidal persons to mental health treatment and preventing reattempts (6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means (e.g., substances,

firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for strategies to include in comprehensive suicide prevention efforts that are based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years because determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed

per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

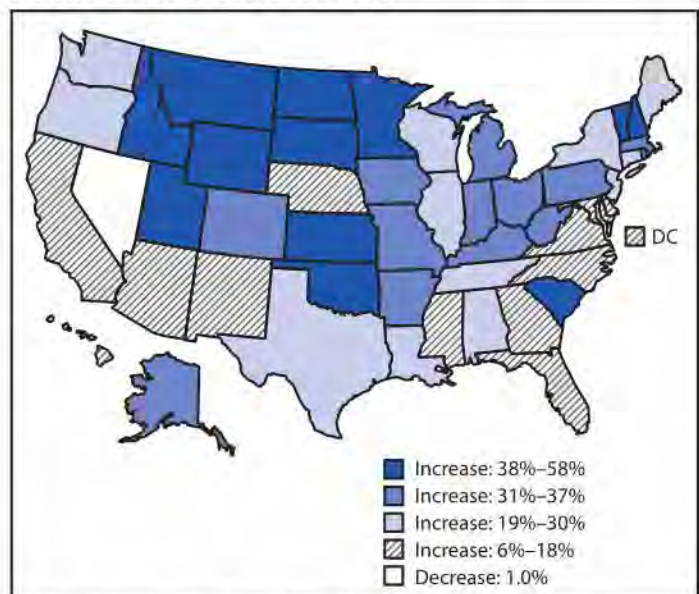

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of problematic alcohol use and other substance use that are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent or impending crises) have been identified as potential risk factors for suicide in NVDRS. Circumstances captured are those identified as contributing to suicide in coroner/medical examiner or law enforcement reports, which reflect information provided by family and friends at the time of death. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using chi-square tests. Logistic regression analyses were used to estimate adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for sex, age group, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall

FIGURE. Percent change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039; 54.0%) were compared with those with known mental health conditions (9,407; 46.0%) for 27 states. Whereas decedents were predominantly male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio [OR] = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide followed by suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had previously served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%), decedents without known mental health conditions were more likely to die by firearm (55.3%) and less likely to die by hanging/strangulation/suffocation (26.9%) or poisoning (10.4%) than were those with known mental health conditions (40.6%, 31.3%, and 19.8%, respectively). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health

conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions (9,407) and approximately 85% of those without known mental health conditions (9,357) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any problematic substance use (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss

(45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and perpetrating interpersonal violence in the past month (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (50.5% versus 47.2%) such as recent criminal legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job/financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and 15.6%, respectively) and those with mental health conditions (21.4%

Abbreviations: CI = confidence interval; NA = not adjusted; NS = not significant; OR = odds ratio.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

<sup>§</sup> OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

<sup>¶</sup> Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for sex, age group, and race/ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely than decedents with mental health conditions to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility, such as an alcohol/substance use treatment facility (24.2% versus 11.6%). Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation

(23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

See table footnotes on next page.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward mental health conditions alone with regard to downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and

other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions also often experienced other circumstances such as relationship problems and job/financial or physical health problems that contributed to their suicide. These findings point to the need to both prevent the circumstances associated with the onset of mental health conditions and support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for mental health or substance use disorders,

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

<sup>§</sup> OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

<sup>¶</sup> Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for sex, age group, and race/ethnicity. Known mental health condition was the reference group.

<sup>\*\*</sup> Includes decedents with one or more diagnosed current mental health conditions, which are not mutually exclusive. Therefore, sums of percentages for the diagnosed conditions exceed 100%. Denominator includes the number of decedents with one or more current diagnosed mental health conditions.

<sup>††</sup> The specific type of mental health condition was calculated only among those with one or more known diagnosed mental health conditions.

<sup>§§</sup> Not a diagnosis.

<sup>¶¶</sup> Denominator is decedents aged  $\geq 18$  years.

<sup>\*\*\*</sup> Denominator is decedents aged 10–18 years.

<sup>†††</sup> Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

<sup>§§§</sup> Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk for suicide, creating organizational and

workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions and other life challenges), strengthening access to and delivery of care, supporting family and friends after a suicide, and encouraging the media to follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental health disorders

## References

## Summary

## What is already known about this topic?

In 2016, nearly 45,000 persons died by suicide in the United States. Mental health conditions are one of several contributors to suicide.

## What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. Relationship, substance use, health, and job or financial problems are among the other circumstances contributing to suicide.

## What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's *Preventing Suicide: A Technical Package of Policy, Programs, and Practices*, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

(13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health conditions in the current study were experiencing mental health challenges that were unknown, undiagnosed, or not reported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: A Technical Package of Policy, Programs, and Practices* (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

### Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are one of several factors contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition.

Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health conditions, including relationship problems/loss (45.1% versus 39.6%), life stressors (50.5% versus 47.2%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among persons in all age groups  $< 75$  years, with adults aged 45–64 having the largest percent increase (45% from 10.2 per 100,000 persons [1999] to 19.2 per 100,000 [2016]) and the greatest number of suicides (232,108) during the same period (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$70 billion per year in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite this call to action, suicide prevention largely focuses on identifying and referring suicidal persons to mental health treatment and preventing reattempts (6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means

(e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for strategies to include in comprehensive suicide prevention efforts that are based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years because determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates

were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

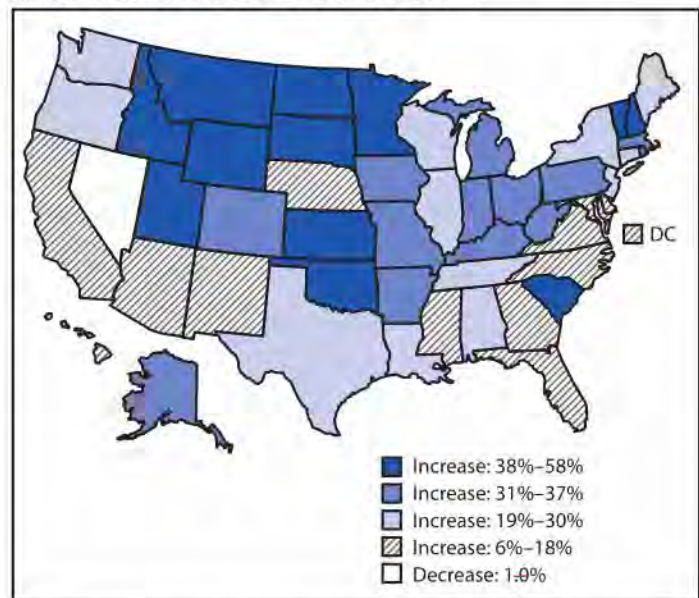

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of problematic alcohol use and other substance use that are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent or impending crises) have been identified as potential risk factors for suicide in NVDRS. Circumstances captured are those identified as contributing to suicide in coroner/medical examiner or law enforcement reports, which reflect information provided by family and friends at the time of death. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using chi-square tests. Logistic regression analyses were used to estimate adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for sex, age group, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table;

**FIGURE. Percent change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016**

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

<https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039; 54.0%) were compared with those with known mental health conditions (9,407; 46.0%) for 27 states. Whereas decedents were predominantly male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio [OR] = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide followed by suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had previously served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%), decedents without known mental health conditions were more likely to die by firearm (55.3%) and less likely to die by hanging/strangulation/suffocation (26.9%) or poisoning (10.4%) than were those with known mental health

See table footnotes on next page.

conditions (40.6%, 31.3%, and 19.8%, respectively). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions (9,407) and approximately 85% of those without known mental health conditions (9,357) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any problematic substance use (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health

or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and perpetrating interpersonal violence in the past month (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (50.5% versus 47.2%) such as criminal legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and

† Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for sex, age group, and race/ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

job/financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and 15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely than decedents with mental health conditions to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility, such as an alcohol/substance use treatment facility (24.2% versus 11.6%). Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward mental health conditions alone with regard to downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and

other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions also often experienced other circumstances such as relationship problems and job/financial or physical health problems that contributed to their suicide. These findings point to the need to both prevent the circumstances associated with the onset of mental health conditions and support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for mental health or substance use

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

<sup>§</sup> OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

<sup>¶</sup> Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for sex, age group, and race/ethnicity. Known mental health condition was the reference group.

<sup>\*\*</sup> Includes decedents with one or more diagnosed current mental health conditions, which are not mutually exclusive. Therefore, sums of percentages for the diagnosed conditions exceed 100%. Denominator includes the number of decedents with one or more current diagnosed mental health conditions.

<sup>††</sup> The specific type of mental health condition was calculated only among those with one or more known diagnosed mental health conditions.

<sup>§§</sup> Not a diagnosis.

<sup>¶¶</sup> Denominator is decedents aged  $\geq 18$  years.

<sup>\*\*\*</sup> Denominator is decedents aged 10–18 years.

<sup>†††</sup> Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

<sup>§§§</sup> Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

disorders, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means

among persons at risk for suicide, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions and other life challenges), strengthening access to and delivery of care, supporting family and friends after a suicide, and assuring the media for safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews

## References

## Summary

## What is already known about this topic?

In 2016, nearly 45,000 persons died by suicide in the United States. Mental health conditions are one of several contributors to suicide.

## What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. Relationship, substance use, health, and job or financial problems are among the other circumstances contributing to suicide.

## What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health conditions in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: A Technical Package of Policy, Programs, and Practices* (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

### Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are one of several factors contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition.

Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health conditions, including relationship problems/loss (45.1% versus 39.6%), life stressors (50.5% versus 47.2%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among persons in all age groups  $< 75$  years, with adults aged 45–64 having the largest percent increase (45%; from 13.2 per 100,000 persons [1999] to 19.2 per 100,000 [2016]) and the greatest number of suicides (232,108) during the same period (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$70 billion per year in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite this call to action, suicide prevention largely focuses on identifying and referring suicidal persons to mental health treatment and preventing reattempts (6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means

(e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for strategies to include in comprehensive suicide prevention efforts that are based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years because determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates

were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

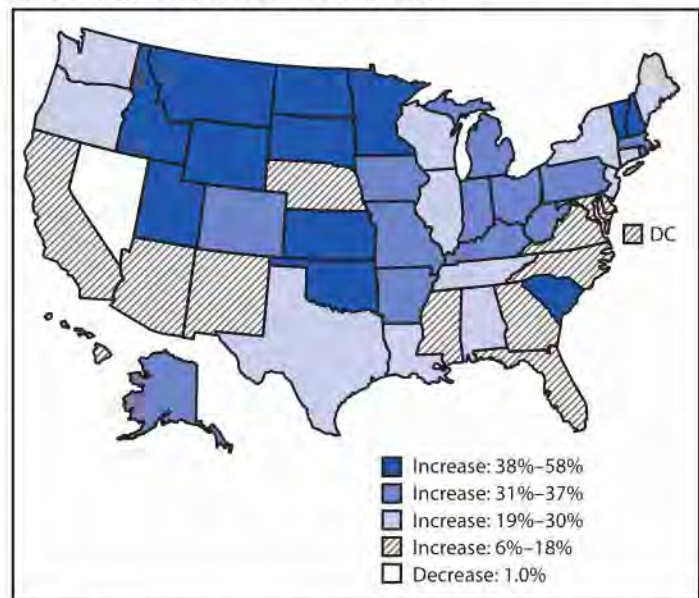

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of problematic alcohol use and other substance use that are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent or impending crises) have been identified as potential risk factors for suicide in NVDRS. Circumstances captured are those identified as contributing to suicide in coroner/medical examiner or law enforcement reports, which reflect information provided by family and friends at the time of death. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using chi-square tests. Logistic regression analyses were used to estimate adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for sex, age group, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table;

**FIGURE. Percent change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016**

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

<https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039; 54.0%) were compared with those with known mental health conditions (9,407; 46.0%) for 27 states. Whereas decedents were predominantly male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio [OR] = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide followed by suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had previously served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%), decedents without known mental health conditions were more likely to die by firearm (55.3%) and less likely to die by hanging/strangulation/suffocation (26.9%) or poisoning (10.4%) than were those with known mental health

See table footnotes on next page.

conditions (40.6%, 31.3%, and 19.8%, respectively). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions (9,407) and approximately 85% of those without known mental health conditions (9,357) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any problematic substance use (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health

or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and perpetrating interpersonal violence in the past month (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (50.5% versus 47.2%) such as criminal legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and

**Abbreviations:** CI = confidence interval; NA = not adjusted; NS = not significant; OR = odds ratio.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

† Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for sex, age group, and race/ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

job/financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and 15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely than decedents with mental health conditions to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility, such as an alcohol/substance use treatment facility (24.2% versus 11.6%). Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

See table footnotes on next page.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward mental health conditions alone with regard to downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and

other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions also often experienced other circumstances such as relationship problems and job/financial or physical health problems that contributed to their suicide. These findings point to the need to both prevent the circumstances associated with the onset of mental health conditions and support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for mental health or substance use

<sup>\*\*\*</sup> Denominator is decedents aged 10–18 years.

<sup>†††</sup> Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

<sup>§§§</sup> Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

disorders, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means

among persons at risk for suicide, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions and other life challenges), strengthening access to and delivery of care, supporting family and friends after a suicide, and assuring the media follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews

## References

## Summary

## What is already known about this topic?

In 2016, nearly 45,000 persons died by suicide in the United States. Mental health conditions are one of several contributors to suicide.

## What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. Relationship, substance use, health, and job or financial problems are among the other circumstances contributing to suicide.

## What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health conditions in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: A Technical Package of Policy, Programs, and Practices* (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

### Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are one of several factors contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition.

Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health conditions, including relationship problems/loss (45.1% versus 39.6%), life stressors (50.5% versus 47.2%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among persons in all age groups  $< 75$  years, with adults aged 45–64 having the largest absolute rate increase (from 13.2 per 100,000 persons [1999] to 19.2 per 100,000 [2016]) and the greatest number of suicides (232,108) during the same period (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$70 billion per year in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite this call to action, suicide prevention largely focuses on identifying and referring suicidal persons to mental health treatment and preventing reattempts (6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means (e.g., substances,

firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for strategies to include in comprehensive suicide prevention efforts that are based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years because determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed

per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

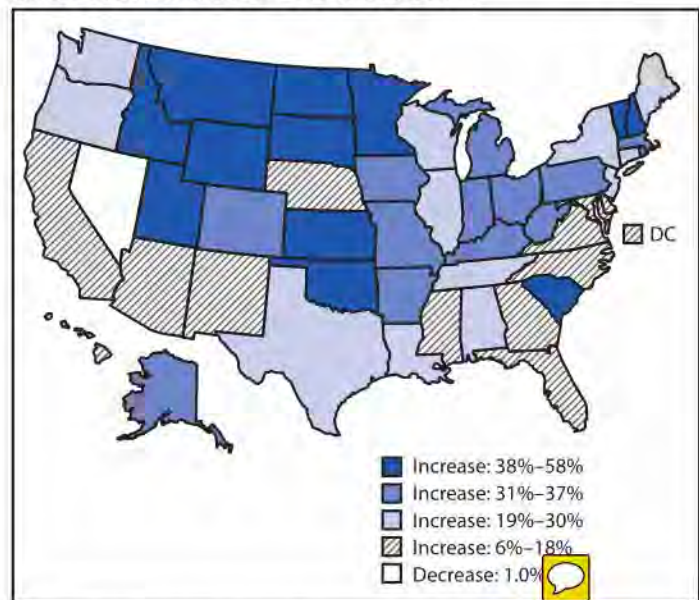

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of problematic alcohol use and other substance use that are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent or impending crises) have been identified as potential risk factors for suicide in NVDRS. Circumstances captured are those identified as contributing to suicide in coroner/medical examiner or law enforcement reports, which reflect information provided by family and friends at the time of death. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using chi-square tests. Logistic regression analyses were used to estimate adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for sex, age group, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall

**FIGURE. Percent change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016**

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039; 54.0%) were compared with those with known mental health conditions (9,407; 46.0%) for 27 states. Whereas decedents were predominantly male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio [OR] = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide followed by suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had previously served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%), decedents without known mental health conditions were more likely to die by firearm (55.3%) and less likely to die by hanging/strangulation/suffocation (26.9%) or poisoning (10.4%) than were those with known mental health conditions (40.6%, 31.3%, and 19.8%, respectively). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health

conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95%, CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions (9,407) and approximately 85% of those without known mental health conditions (9,357) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any problematic substance use (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss

(45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and perpetrating interpersonal violence in the past month (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (50.5% versus 47.2%) such as recent criminal legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job/financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and 15.6%, respectively) and those with mental health conditions (21.4%

**Abbreviations:** CI = confidence interval; NA = not adjusted; NS = not significant; OR = odds ratio.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

† Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

‡ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for sex, age group, and race/ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged  $\geq 10$  years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged  $\geq 18$  years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely than decedents with mental health conditions to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility, such as an alcohol/substance use treatment facility (24.2% versus 11.6%). Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation (23.0%)

or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases  $>30\%$ . Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often

oriented toward mental health conditions alone with regard to downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions also often experienced other circumstances such as relationship problems and job/financial or physical health problems that contributed to their suicide. These findings point to the need to both prevent the circumstances associated with the onset of mental health conditions and support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for mental health or substance use disorders, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including

<sup>†††</sup> Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

<sup>§§§</sup> Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk for suicide, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions

and other life challenges), strengthening access to and delivery of care, supporting family and friends after a suicide, and encouraging the media to follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental health disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental

## References

## Summary

## What is already known about this topic?

In 2016, nearly 45,000 persons died by suicide in the United States. Mental health conditions are one of several contributors to suicide.

## What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. Relationship, substance use, health, and job or financial problems are among the other circumstances contributing to suicide.

## What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

health conditions in the current study were experiencing mental health challenges that were unknown or not reported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: A Technical Package of Policy, Programs, and Practices* (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

5 **Structured abstract (245/250 words—this word count is not included in the 1800 max for the remainder)**

6 **Background:** Suicide rates have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor  
7 contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform  
8 comprehensive state suicide prevention planning.

9 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
10 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
11 for 50 states and Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27  
12 states in 2015, were used to examine contributing circumstances among decedents with and without known  
13 MHP.

14 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
15 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
16 half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, those  
17 without known MHP were more likely (all  $p \leq 0.05$ ) than those with a MHP to have relationship problems/loss  
18 (45.1% vs 39.6%), life stressors/loss (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), but these  
19 circumstances were common across groups.

20 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
21 contributed to suicides among people with and without known MHP.

22 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
23 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
24 friends/family after a suicide occurs.

25 **INTRODUCTION**

26 **BACKGROUND AND PURPOSE (255/250 words)**

27 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
28 ≥10 years old [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and  
29 urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
30 are *increasing* [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
31 for suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the  
32 nation more than \$69 billion in direct medical and work loss costs [1].

33 The *National Strategy for Suicide Prevention (NSSP)* [5] calls for a public health approach to suicide prevention  
34 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
35 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
36 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
37 mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems,  
38 access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-  
39 solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that

contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## **METHODS (2526/250 words)**

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders [and syndromes](#) listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9], [with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. For this study, alcohol and other substance use disorders were not defined as MHP, and were examined in both groups.](#) NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## **RESULTS (58984/600 words)**

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases more than 30% observed in 25 states [\(Table 1, Figure 1\)](#).

Modeled suicide rate trends indicated significant increases for 44 states, [as well as for the U.S. overall \(Table 1\) and for males \(34 states\) and females \(43 states\), as well as for the U.S. overall \(Table 1\).](#) ~~By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females.~~ Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407; [all chi-square and logistic regression analyses significant at  \$p < .05\$](#) ). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR

= 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

Although firearms were used most often, overall (48.5%), decedents with known MHP were more likely to die by suffocation (31.3 vs. 26.9%) and poisoning (19.8% vs. 10.4%) than those without known MHP.

All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available circumstances information (Table 3). People without known MHP were less likely to have any substance abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without known MHP, versus those with known MHP had a significantly greater likelihood (p<.01) of any relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They were also significantly more likely to have experienced other life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common crises were intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

Decedents without known MHP had significantly lower odds of recent release (aOR=0.5 95% CI (0.4-0.5)) from any institution, but among those who were recently released (5.1%), ~~those without a known MHP~~ they were significantly more likely to be released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 462.78% of this group were released from psychiatric facilities.

Decedents without known MHP, compared to those with MHP, were less likely to have a history of suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in five people in both groups disclosed suicide intent frequently, (22.4% vs. 24.5%), ~~respectively~~.

## 110 **Conclusions and Comments (67580/700 words)**

From 1999-2016, 44 states saw significant suicide rate increases. Half of the states experienced increases of 30% or more. ~~Rates increased significantly in 34 states among males and 43 states among females. More~~ Additional research into the specific causes of these trends is necessary [10]. Fortunately, data from the states participating in NVDRS can shed light on the understanding the contributing circumstances that contributed to of suicide recent suicides is essential for prevention practice and help guide prevention activities. decision-making.

117

Researchers and practitioners regularly state that suicide is not caused by a single factor, however, the focus of suicide research and prevention practices, almost solely, focus on identify and treating MHP. The current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal deliberation [10].

Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over half were in current treatment. This suggests that additional supports for this population are needed to keep

them safe. This includes broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems needed that integrate physical and behavioral health and that better support suicide prevention and patient safety, especially through care transitions [11].

Study findings indicate that people with known MHP also experienced other life stressors such as job/financial, relationship, and/or physical health problems. These findings point to the need to both prevent the conditions associated with mental health problems in the first place and the need to support people with known MHP to decrease their risk of poor social, health, and economic outcomes [12].

These results, together, underscore the importance of comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, and identifying and better supporting people at risk. Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning and implementing such a comprehensive approach to suicide prevention [13].

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS is not yet nationally representative; the 27 states included in the current study represent 49.6% of the U.S. population. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to ~~MHP and substance abuse disorders, mental disorders~~ [14], however many methodological variations across studies exist [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and prioritize evidence-based comprehensive suicide prevention.

1 **Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

2 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
3 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

4 **Structured abstract (245/250 words—this word count is not included in the 1800 max for the remainder)**

5 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP)  
6 are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing  
7 circumstances can inform comprehensive state suicide prevention planning.

8 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
9 consecutive three-year periods (1999–2016), were assessed using data from the National Vital Statistics System  
10 for 50 states and Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27  
11 states in 2015, were used to examine contributing circumstances among decedents with and without known  
12 MHP.

13 **Results:** From 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
15 half (54.0%) of decedents did not have a known MHP. Among decedents with circumstance information, those  
16 without known MHP were more likely (all  $p \leq .01$ ) than those with a MHP to have relationship problems/loss  
17 (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), but these  
18 circumstances were common across groups.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999–2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

24 **INTRODUCTION**

25 **BACKGROUND AND PURPOSE**

26 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
27 ≥10 years old [1]. Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and  
28 urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
29 are increasing [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
30 for suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the  
31 nation more than \$69 billion in direct medical and work loss costs [1].

32 The *National Strategy for Suicide Prevention* (NSSP) [5] calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
35 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
36 mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems,  
37 access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-  
38 solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that  
39 contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of

**Comment [snk6]:**

This title seems in opposition to the order of our presentation framework – first we present \*what\* – the trends – and then we talk about \*why\* – the contributing circumstances.

**Comment [snk6]:**

Without this, the context/geography isn't fully set.

The MMWR editors might want "U.S." and the study years included in the title at some point.

**Comment [snk6]:**

This important "factoid" appears in three places in this report. The phrase "30% or more" is technically correct, although the phrase "more than 30%" is even more correct (the lower limit to the range for the 25 highest states is about 32% -- and no state is right at 30% even when rounding). Regardless of which phrase we adopt, it seems that we should be consistent throughout. I made a suggested revision further below (in the Results) assuming that we are going with "30% or more".

reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9], with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases ~~more than 30% of 30% or more~~ observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407; all chi-square and logistic regression analyses significant at  $p \leq .05$ ). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

Comment [snk6]:

For consistency. See comments above.

85 Although firearms were used most often overall (48.5%), decedents with known MHP were more likely to die by  
86 suffocation (31.3 vs. 26.9%) and poisoning (19.8% vs. 10.4%) than those without known MHP.

87 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
88 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
89 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
90 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

91 Decedents without known MHP, versus those with known MHP had a significantly greater likelihood ( $p<.01$ ) of  
92 any relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
93 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
94 were also significantly more likely to have experienced other life stressors (54.2% vs 49.7%), such as criminal-  
95 legal problems (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had  
96 a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common  
97 crises were intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

98 Decedents without known MHP had significantly lower odds of recent release (aOR=0.5 95% CI (0.4-0.5) from  
99 any institution, but among those who were recently released (5.1%), they were significantly more likely to be  
100 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
101 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
102 group were released from psychiatric facilities.

103 Decedents without known MHP, compared to those with MHP, were less likely to have a history of suicidal  
104 ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in five  
105 people in both groups disclosed suicide intent (22.4% vs. 24.5%).

## 106 **Conclusions and Comments**

107 From 1999-2016, 44 states saw significant suicide rate increases. Half of the states experienced increases of 30%  
108 or more. Additional research into the specific causes of these trends is necessary. Fortunately, data from the  
109 states participating in NVDRS can shed light on the circumstances that contributed to recent suicides and help  
110 guide prevention activities.

111 Researchers and practitioners regularly state that suicide is not caused by a single factor, however, the focus of  
112 suicide research and prevention practices, almost solely, focus on identify and treating MHP. The current study  
113 found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more  
114 relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or  
115 impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts  
116 occur with minimal deliberation [10].

117 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
118 half were in current treatment. This suggests that additional supports for this population are needed to keep  
119 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
120 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
121 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems  
122 needed that integrate physical and behavioral health and that better support suicide prevention and patient  
123 safety, especially through care transitions [11].

124 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
125 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions

126 associated with mental health problems in the first place and the need to support people with known MHP to  
127 decrease their risk of poor social, health, and economic outcomes [12].

128 These results, together, underscore the importance of comprehensive statewide suicide prevention activities  
129 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
130 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
131 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
132 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
133 emotional, and social support, and identifying and better supporting people at risk. Other strategies include  
134 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
135 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
136 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
137 reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning  
138 and implementing such a comprehensive approach to suicide prevention [13].

139 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
140 UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing  
141 suicide rates potentially biasing reported suicide rates downward), or decreased percentages of such deaths  
142 over time (i.e. increasing suicide rates potentially biasing estimated rate trends upward). Second, NVDRS is not  
143 yet nationally representative; the 27 states included in the current study represent 49.6% of the U.S. population  
144 [1]. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore,  
145 the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
146 interviews with next-of-kin often see greater attributions to mental disorders [14], however many  
147 methodological variations across studies exist [15]. It is likely that some people without known MHP in the  
148 current study were experiencing mental health challenges that were unknown, and hence unreported by key  
149 informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of  
150 addressing the broad range of contributing circumstances.

151 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
152 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
153 *Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and  
154 prioritize evidence-based comprehensive suicide prevention.

#### Comment [snk6]:

These alternate parenthetical phrases might be considered again.

The current ones confused me when I first read them, and although I was able to determine what they were intended to convey, that might only be due to my participation in the discussion with NCHS.

In the first parenthetical phrase, which basically refers to Maryland, it sounds like we're saying that decreasing rates might be the anticipated result. But Maryland's reported rates didn't decrease – they increased despite the large and persistent percentage of injury deaths with undetermined intent. They might not have increased as much as they would have with more complete reporting of intent, and if that is true then we are looking at an increase that is biased downward. Or their reported rates might be biased downward across the board.

For the second parenthetical phrase, which basically refers to Massachusetts, Rhode Island, and Utah, it sounds as though we might be attributing the increase in reported rates to the decrease in the percentage of injury deaths of undetermined intent. But the observed increases, especially in Utah, might be too large to be explained by this alone. More likely, it would have biased already increasing rate trends further upwards.

4 **Structured abstract (245/250 words—this word count is not included in the 1800 max for the remainder)**

5 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP)  
6 are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing  
7 circumstances can inform comprehensive state suicide prevention planning.

8 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
9 consecutive three-year periods (1999–2016), were assessed using data from the National Vital Statistics System  
10 for 50 states and Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27  
11 states in 2015, were used to examine contributing circumstances among decedents with and without known  
12 MHP.

13 **Results:** From 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more of more than 30%. Rates increased significantly among males and females, in 34 and 43 states,  
15 respectively. Over half (54.0%) of decedents did not have a known MHP. Among decedents with circumstance  
16 information, several circumstances, including those without known MHP were more likely (all  $p < .01$ ) than those  
17 with a MHP to have relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and  
18 recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a known MHP,  
19 but these circumstances were common across groups.

20 **Conclusions:** Suicide rates increased significantly across most states from 1999–2016. Various circumstances  
21 contributed to suicides among people with and without known MHP.

22 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
23 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
24 friends/family after a suicide occurs.

25 **INTRODUCTION**

26 **BACKGROUND AND PURPOSE**

27 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
28 ≥10 years old [1]. Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and  
29 urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
30 are increasing [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
31 for suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the  
32 nation more than \$69 billion in direct medical and work loss costs [1].

33 The *National Strategy for Suicide Prevention* (NSSP) [5] calls for a public health approach to suicide prevention  
34 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
35 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
36 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
37 mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems,  
38 access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-  
39 solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that

**Comment [tgs9]:** I think we need a transition like this to avoid implying that the circumstances listed are the only significant differences.

**Comment [tgs9]:** You had changed this to .05. I don't think we need this in the abstract since we say they were significant. Just saying this is consistent with the aOR too.

contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9], with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was significant for +1.1% for males (+1.1%) and females (+2.6%) for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407); all chi-square and logistic regression analyses significant at  $p \leq .05$ . While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (aOR range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2, 95% CI = 1.1-1.3).

**Comment [tgs9]:** We can't include this here because not all of the comparisons were significant. I added some text below to address this.

**Comment [tgs9]:** I realized that we split up the results about methods and that our toxicology results are incomplete. I suggest moving these down.

Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

~~Although While~~ firearms were ~~the most common method overall used most often overall~~ (48.5%) ~~and for both groups~~, decedents without known MHP were more likely to die by ~~firearm~~ (55.3% vs. 40.6%) ~~and less likely to die by~~ suffocation (~~26.9% vs 31.3%~~) ~~vs. 26.9%~~ ~~or and~~ poisoning (~~10.4% vs 19.8%~~) ~~vs. 10.4%~~ than those without known MHP. These differences remained significant in the adjusted models.

Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95% CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

All suicide decedents with ~~known~~-MHP (N=9,407) and approximately 85% without ~~known~~ MHP (N=9,357) had available circumstances information (Table 3). People without known MHP were less likely to have any substance abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without known MHP, versus those with known MHP had a ~~significantly~~ greater likelihood (~~p<.01~~) of any relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They were also ~~significantly~~ more likely to have experienced other life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models. Among those with crises, intimate partner and physical health problems were the most common types for both groups and did not differ between them. Among both groups, the most common crises were intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

Decedents without known MHP had significantly lower odds of recent release (aOR=0.5 95% CI (0.4-0.5) from any institution, but among those who were recently released (5.1%), they were significantly more likely to be released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this group were released from psychiatric facilities.

Decedents without known MHP, compared to those with MHP, were less likely to have a history of suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in five people in both groups disclosed suicide intent (22.4% vs. 24.5%).

## Conclusions and Comments

From 1999-2016, 44 states saw significant suicide rate increases. Half of the states experienced increases of ~~30% more than 30% or more~~. Additional research into the specific causes of these trends is necessary. Fortunately, data from the states participating in NVDRS can shed light on the circumstances that contributed to recent suicides and help guide prevention activities.

Researchers and practitioners regularly state that suicide is not caused by a single factor, however, the focus of suicide research and prevention practices, almost solely, focus on identify and treating MHP. The current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more

125 relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or  
126 impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts  
127 occur with minimal deliberation [10].

128 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
129 half were in current treatment. This suggests that additional supports for this population are needed to keep  
130 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
131 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
132 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems  
133 needed that integrate physical and behavioral health and that better support suicide prevention and patient  
134 safety, especially through care transitions [11].

135 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
136 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
137 associated with mental health problems in the first place and the need to support people with known MHP to  
138 decrease their risk of poor social, health, and economic outcomes [12].

139 These results, together, underscore the importance of comprehensive statewide suicide prevention activities  
140 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
141 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
142 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
143 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
144 emotional, and social support, and identifying and better supporting people at risk. Other strategies include  
145 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
146 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
147 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
148 reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning  
149 and implementing such a comprehensive approach to suicide prevention [13].

150 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
151 UT) might have been impacted by large proportions of injury deaths of undetermined intent (~~i.e. decreasing~~  
152 ~~suicide rates~~), ~~potentially biasing reported suicide rates downward~~) or decreased percentages of such deaths  
153 over time (~~i.e. increasing suicide rates potentially biasing estimated rate trends upward~~). Second, NVDRS is not  
154 yet nationally representative; the 27 states included in the current study represent 49.6% of the U.S. population  
155 [1]. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore,  
156 the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
157 interviews with next-of-kin often see greater attributions to mental disorders [14], however many  
158 methodological variations across studies exist [15]. It is likely that some people without known MHP in the  
159 current study were experiencing mental health challenges that were unknown, and hence unreported by key  
160 informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of  
161 addressing the broad range of contributing circumstances.

162 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
163 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
164 *Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and  
165 prioritize evidence-based comprehensive suicide prevention.

4 **Structured abstract (245/250 words—this word count is not included in the 1800 max for the remainder)**

5 **Background:** Suicide rates have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor  
6 contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform  
7 comprehensive state suicide prevention planning.

8 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
9 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
10 for 50 states and Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27  
11 states in 2015, were used to examine contributing circumstances among decedents with and without known  
12 MHP.

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
15 half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, several  
16 circumstances, including those without known MHP were more likely (all  $p < .01$ ) than those with a MHP to have  
17 relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9%  
18 vs 26.0%), were significantly more likely among those without a known MHP, but these circumstances were  
19 common across groups.

20 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
21 contributed to suicides among people with and without known MHP.

22 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
23 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
24 friends/family after a suicide occurs.

## 25 INTRODUCTION

### 26 BACKGROUND AND PURPOSE

27 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
28 ≥10 years old [1]. Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and  
29 urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
30 are *increasing* [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
31 for suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the  
32 nation more than \$69 billion in direct medical and work loss costs [1].

33 The *National Strategy for Suicide Prevention*(NSSP) [5] calls for a public health approach to suicide prevention  
34 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
35 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
36 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
37 mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems,  
38 access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-  
39 solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that

**Comment [tgs9]:** I think we need a transition like this to avoid implying that the circumstances listed are the only significant differences.

**Comment [tgs9]:** You had changed this to .05. I don't think we need this in the abstract since we say they were significant. Just saying this is consistent with the aOR too.

contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9], with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was significant for +1.1% for males (+1.1%) and females (+2.6%) for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407); all chi-square and logistic regression analyses significant at  $p \leq .05$ . While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio (OR) range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2, 95% CI = 1.1-1.3).

**Comment [tgs9]:** We can't include this here because not all of the comparisons were significant. I added some text below to address this.

**Comment [tgs9]:** I realized that we split up the results about methods and that our toxicology results are incomplete. I suggest moving these down.

85 Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were  
86 currently serving, in the U.S. military.

87

88 ~~Although While~~ firearms were ~~the most common method overall used most often overall~~ (48.5%) ~~and for both~~  
89 ~~groups~~, decedents without known MHP were more likely to die by ~~firearm~~ (55.3% vs. 40.6%) ~~and less likely to~~  
90 ~~die by~~ suffocation (~~26.9% vs 31.3%~~) ~~vs. 26.9%~~ ~~or and~~ poisoning (~~10.4% vs 19.8%~~) ~~vs. 10.4%~~ than those without  
91 known MHP. These differences remained significant in the adjusted models.

92 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
93 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
94 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

95 All suicide decedents with ~~known~~-MHP (N=9,407) and approximately 85% without ~~known~~ MHP (N=9,357) had  
96 available circumstances information (Table 3). People without known MHP were less likely to have any  
97 substance abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history  
98 of mental health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

99 Decedents without known MHP, versus those with known MHP had a ~~significantly~~ greater likelihood (~~p<.01~~) of  
100 any relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
101 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
102 were also ~~significantly~~ more likely to have experienced other life stressors (54.2% vs 49.7%), such as criminal-  
103 legal problems (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had  
104 a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained  
105 significant in the adjusted models. Among those with crises, intimate partner and physical health problems were  
106 the most common types for both groups and did not differ between them. Among both groups, the most  
107 common crises were intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%),  
108 respectively.

109 Decedents without known MHP had significantly lower odds of recent release (aOR=0.5 95% CI (0.4-0.5) from  
110 any institution, but among those who were recently released (5.1%), they were significantly more likely to be  
111 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
112 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
113 group were released from psychiatric facilities.

114 Decedents without known MHP, compared to those with MHP, were less likely to have a history of suicidal  
115 ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in five  
116 people in both groups disclosed suicide intent (22.4% vs. 24.5%).

## 117 Conclusions and Comments

118 From 1999-2016, 44 states saw significant suicide rate increases. Half of the states experienced increases of 30%  
119 or more. Additional research into the specific causes of these trends is necessary. Fortunately, data from the  
120 states participating in NVDRS can shed light on the circumstances that contributed to recent suicides and help  
121 guide prevention activities.

122 Researchers and practitioners regularly state that suicide is not caused by a single factor, however, the focus of  
123 suicide research and prevention practices, almost solely, focus on identify and treating MHP. The current study  
124 found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more

relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal deliberation [10].

Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over half were in current treatment. This suggests that additional supports for this population are needed to keep them safe. This includes broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems needed that integrate physical and behavioral health and that better support suicide prevention and patient safety, especially through care transitions [11].

Study findings indicate that people with known MHP also experienced other life stressors such as job/financial, relationship, and/or physical health problems. These findings point to the need to both prevent the conditions associated with mental health problems in the first place and the need to support people with known MHP to decrease their risk of poor social, health, and economic outcomes [12].

These results, together, underscore the importance of comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, and identifying and better supporting people at risk. Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning and implementing such a comprehensive approach to suicide prevention [13].

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS is not yet nationally representative; the 27 states included in the current study represent 49.6% of the U.S. population [1]. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders [14], however many methodological variations across studies exist [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and prioritize evidence-based comprehensive suicide prevention.

4 **Structured abstract (245/250 words—this word count is not included in the 1800 max for the remainder)**

5 **Background:** Suicide rates have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor  
6 contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform  
7 comprehensive state suicide prevention planning.

8 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
9 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
10 for 50 states and Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27  
11 states in 2015, were used to examine contributing circumstances among decedents with and without known  
12 MHP.

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
15 half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, those  
16 without known MHP were more likely (all  $p \leq .01$ ) than those with a MHP to have relationship problems/loss  
17 (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), but these  
18 circumstances were common across groups.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

## 24 INTRODUCTION

### 25 BACKGROUND AND PURPOSE

26 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
27 ≥10 years old [1]. Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and  
28 urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
29 are *increasing* [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
30 for suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the  
31 nation more than \$69 billion in direct medical and work loss costs [1].

32 The *National Strategy for Suicide Prevention*(NSSP) [5] calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
35 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
36 mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems,  
37 access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-  
38 solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that  
39 contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of

reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9], with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407; all chi-square and logistic regression analyses significant at  $p \leq .05$ ). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

85 Although firearms were used most often overall (48.5%), decedents with known MHP were more likely to die by  
86 suffocation (31.3 vs. 26.9%) and poisoning (19.8% vs. 10.4%) than those without known MHP.

87 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
88 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
89 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
90 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

91 Decedents without known MHP, versus those with known MHP had a significantly greater likelihood ( $p<.01$ ) of  
92 any relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
93 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
94 were also significantly more likely to have experienced other life stressors (54.2% vs 49.7%), such as criminal-  
95 legal problems (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had  
96 a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common  
97 crises were intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

98 Decedents without known MHP had significantly lower odds of recent release (aOR=0.5 95% CI (0.4-0.5) from  
99 any institution, but among those who were recently released (5.1%), they were significantly more likely to be  
100 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
101 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
102 group were released from psychiatric facilities.

103 Decedents without known MHP, compared to those with MHP, were less likely to have a history of suicidal  
104 ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in five  
105 people in both groups disclosed suicide intent (22.4% vs. 24.5%).

## 106 **Conclusions and Comments**

107 From 1999-2016, 44 states saw significant suicide rate increases. Half of the states experienced increases of 30%  
108 or more. Additional research into the specific causes of these trends is necessary. Fortunately, data from the  
109 states participating in NVDRS can shed light on the circumstances that contributed to recent suicides and help  
110 guide prevention activities.

111 Researchers and practitioners regularly state that suicide is not caused by a single factor, however, the focus of  
112 suicide research and prevention practices, almost solely, focus on identify and treating MHP. The current study  
113 found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more  
114 relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or  
115 impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts  
116 occur with minimal deliberation [10].

117 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
118 half were in current treatment. This suggests that additional supports for this population are needed to keep  
119 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
120 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
121 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems  
122 needed that integrate physical and behavioral health and that better support suicide prevention and patient  
123 safety, especially through care transitions [11].

124 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
125 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions

associated with mental health problems in the first place and the need to support people with known MHP to decrease their risk of poor social, health, and economic outcomes [12].

These results, together, underscore the importance of comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, and identifying and better supporting people at risk. Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning and implementing such a comprehensive approach to suicide prevention [13].

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS is not yet nationally representative; the 27 states included in the current study represent 49.6% of the U.S. population [1]. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders [14], however many methodological variations across studies exist [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and prioritize evidence-based comprehensive suicide prevention.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

<sup>§</sup> Logistic regression was used to estimate adjusted odds ratio with 95% CIs after controlling for age, sex, race and ethnicity.

<sup>¶</sup> Decedents were aged 10 years and older, as per standard in the suicide prevention literature.

\*\*Denominator is decedents aged 18 years of age and older with reported military service status.

†† Denominator is decedents who died by poisoning, including overdose.

§§ Denominator is decedents with any toxicology tested.

¶¶ Denominator for each positive group is the number tested for the substance in that group.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

Comment [HJ]: Insert "National Vital Statistics System"

Comment [HJ]: Consider sorting state abbreviations alphabetically instead of state names.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

**Percentage Changes in Annual Suicide Rates (per 100,000, Age-Adjusted)**  
2014-2016 Compared Against 1999-2001

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts are largely clinically-oriented, focused on treating mental health problems (MHP) and preventing re-attempts (6). Apart from MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes

state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (665)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
85 These differences remained significant in the adjusted models.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

89 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
90 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
91 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
92 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship  
94 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
95 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely  
96 to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or  
97 eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or  
98 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
99 Among all people with crises, intimate partner problems were the most common types and did not differ by  
100 group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and  
101 job/financial problems (15.6% and 16.8%) were commonly experienced and did not differ by group.

102 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
103 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
104 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
105 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
106 group were released from psychiatric facilities.

107 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
108 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
109 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 110 Conclusions and Comments

111 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
112 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
113 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
114 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
115 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
116 circumstances and can help states identify prevention priorities.

117 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention  
118 research and practice is heavily oriented towards downstream treatment of MHP and prevention of reattempts.  
119 Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as  
120 the current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This  
121 group suffered more from relationship problems and other life stressors such as criminal-legal matters,  
122 eviction/loss of home, and recent or impending crises.

123 Similarly, people with MHP also experienced other life stressors such as job/financial, relationship, and/or  
124 physical health problems. These findings point to the need to both prevent the conditions associated with

Comment [HDE(): I would add in the %  
for opioids as it is timely and relevant

Comment [HDE(): I thought they were  
also 2x likely to be released from other  
facility which included drug rehab?

mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

207 **Word Count:** 1868/1800

1 **Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

2 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
3 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

4 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. ~~Mental health problems (MHP)~~  
5 ~~are just one factor contributing to suicide.~~ Examining state-level trends in ~~suicide~~ and ~~other the multiple~~  
6 contributing circumstances ~~to, suicide~~ can inform comprehensive state suicide prevention planning.

7 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
8 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
9 for 50 states and Washington, D.C. Data from the National Violent Death Reporting System (NVDRS), covering  
10 27 states in 2015, were used to examine contributing circumstances among decedents with and without known  
11 ~~MHP~~ mental health problems (MHP).

12 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
13 of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively.  
14 ~~Among decedents in NVDRS decedents in 27 states, 54.0% half (54.0%) of decedents did not have a known~~  
15 ~~MHP. Among decedents-people~~ with circumstance information, several circumstances, including relationship  
16 problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), **health problems (23.2 vs 21.4%)** and  
17 recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a known MHP  
18 than decedents with MHP, but were common across groups.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

24 **INTRODUCTION**

25 **BACKGROUND AND PURPOSE**

26 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
27 ≥10 years old (1). Between 1999 and 2015, suicide rates increased across ~~both~~ sexes, racial/ethnic groups, and  
28 urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
29 are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
30 for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the  
31 nation more than \$69 billion in direct medical and work loss costs (1).

32 The *National Strategy for Suicide Prevention* (NSSP) (5) calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.

35 Despite the NSSP guidance, suicide prevention efforts largely focus on ~~identifying and treating individuals~~  
36 ~~with clinically-oriented interventions-mental health focused on mental health~~ problems (MHP) ~~or and providing~~  
37 ~~follow-up care to people who have attempted preventing re-attempts suicide~~ (6). ~~Apart from these risks,~~ Other  
38 contributing circumstances include social ~~isolation, relationship problems, and~~ economic problems, access to  
39 lethal means (e.g., substances, firearms, bridges) among people at risk, ~~and~~ poor coping and problem-solving  
40 skills ~~and prior suicide attempts~~ (5). Expanded awareness of these additional circumstances ~~that contributing~~

**Comment [FC]:** I think some sort of clarification is needed to distinguish from previous two sentences since what is reported here are not data on full examined time period or all 50 states. Tracked an idea but there are likely other ways to clarify.

**Comment [zat9]:** Updated

to suicide risk ~~apart from MHP~~, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

**Comment [FC]:** Suggest pulling out the references to tables 2 and 3 since table 1 hasn't been mentioned yet and helps saves on word count. If you want to keep them in, suggest adding "table 1" somewhere into the above paragraph.

**Comment [za19]:** Took the ref to tables out.

**Comment [FC]:** Given attention to this particular at-risk population in the results, made me wonder if some mention of needs of this group should be in the discussion. There are other higher risk groups described below. A consideration could be in the discussion about prevention needs of underserved areas (bottom of page 3) some phrasing could be added about the need for services for higher risk groups, such as those who have served in the military and those who have difficulties, such as MPH, intimate partner problems, have physical health problems, and have financial and legal difficulties. Or on page 4 where "identifying and better supporting people at risk" is stated an e.g. could be added.

**Comment [za19]:** Did not end up adding this as it seemed odd to call out this one population.

85 While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents  
86 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
87 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
88 These differences remained significant in the adjusted models.

89 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
90 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
91 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

92 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
93 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
94 problems (aOR=0.7, 95% CI=0.7-0.8) or job/financial problems (aOR=0.9, 95% CI (0.8-1.0)). While two-thirds of  
95 those with known MHP had a history of mental health or substance abuse treatment (67.2%), just over half  
96 (54.0%) were in current treatment.

97 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
98 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
99 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
100 were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
101 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), or health problems (23.2% and 21.4%) and they were  
102 more likely to have had a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these  
103 differences remained significant in the adjusted models. Among those with crises, intimate partner and physical  
104 health problems were the most common types for both groups and did not differ between them.

105 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
106 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
107 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
108 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
109 group were released from psychiatric facilities.

110 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
111 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people  
112 in both groups disclosed suicide intent (22.4% vs. 24.5%).

### 113 Conclusions and Comments

114 From 1999-2016, 44 states saw significant ~~suicide rate increases~~ increases in suicide rates and 25 states  
115 experienced rate increases of more than 30%. Rates increased significantly ~~for among~~ males, (in 34 states); and  
116 ~~for~~ females; (in 43 states). This finding is consistent with prior research showing a decreasing gender gap in  
117 male-female suicide rates between 1999-2014 (3). ~~Overall, half of the states experienced substantial increases in~~  
118 ~~suicide rates of more than 30%~~. Additional research into the specific causes of these trends is necessary.  
119 Fortunately, data from the 27 states participating in NVDRS ~~can shed light on~~ provides important insight into the  
120 suicide circumstances and circumstances that contributed to recent suicides, and can help states identify  
121 prevention priorities, help guide prevention activities.

122 ~~Researchers and practitioners~~ Suicidologists regularly state that ‘suicide ‘is not caused by a single factor;’ (5)  
123 however, suicide prevention research and practice ~~prevention practices often focus on~~ is heavily weighted  
124 towards identifying and treating MHP clinically-oriented activities focused on MHP (6). In contrast, ~~t~~ The current  
125 study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group

Comment [FC]: It appears non-MHP is being compared to non-MHP. Tracked what I think the edit is but please double check.

Comment [za19]: You are correct. Should be with in the second instances, not without.

126 ~~experienced suffered more~~ relationship problems/issues and ~~other~~ life stressors such as criminal-legal-matters,  
127 ~~housing eviction/loss of home, and health problems. They also experienced more and~~ recent/~~or~~ impending crises  
128 ~~(which may indicate suicides —This is particularly noteworthy in light of findings that suggest that took place~~  
129 ~~many suicides and attempts occur w/with~~ minimal deliberation (10)). ~~Similarly,~~

130 Among people with MHP ~~struggled more with~~ job/financial problems and substance abuse and also commonly  
131 ~~experienced arguments/conflicts, intimate partner,~~ health problems, and other life stressors. These findings all  
132 align with a large literature suggesting vulnerability to such socio-economic and health problems among people  
133 with mental health disorders (11).

134 These results suggest that broader prevention outside of clinical settings is necessary. This can include:  
135 educating the public to know the warning signs of suicide and how to respond, especially if someone discloses  
136 suicide intent; strengthening economic supports (e.g., through housing stabilization policies, household financial  
137 support); creating protective environments (e.g., reducing access to lethal means among people at risk,  
138 implementing workplace policies conducive to help-seeking and encouraging overall well-being, and zoning to  
139 reduce alcohol-outlet density); teaching coping and problem-solving skills early in life to foster lifelong healthy  
140 relationships; and promoting social connectedness to increase one's sense of belonging and access to resources.

141 To address findings that ~~t~~-two-thirds of people with MHP had a history of ~~any treatment mental health and/or~~  
142 ~~substance abuse treatment and over half 54% were in current treatment when they died, states and~~  
143 ~~communities can~~. This suggests that additional supports for this population are needed to keep them safe. This  
144 includes broader implementation of affordable and effective evidence-based treatment modalities (e.g., such as  
145 doctor-patient collaborative care, ~~models and cognitive-behavioral therapy), provide~~ ~~Additionally, greater~~  
146 access to behavioral health providers (especially in underserved areas) ~~is needed, as and encourage greater is~~  
147 ~~expansion of healthcare systems to integration of~~ physical and behavioral health that better support suicide  
148 ~~prevention and patient safety within healthcare systems, especially through care transitions~~ (12).

149 ~~Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,~~  
150 ~~relationship, and/or physical health problems. These findings point to the need to both prevent the conditions~~  
151 ~~associated with mental health problems in the first place, and to support people with known MHP to decrease~~  
152 ~~their risk of poor social, health, and economic outcomes~~ (11).

153 Finally, Together, these results underscore the importance of comprehensive statewide suicide prevention  
154 activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
155 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
156 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
157 life; promoting social connectedness to increase a sense of belongingness and access to informational,  
158 emotional, and social support; and identifying and better supporting people at risk. Other strategies include it is  
159 essential to address risk associated with suicide loss itself. ~~creating protective environments (e.g., reducing~~  
160 ~~access to lethal means among people at risk, creating organizational and workplace policies to promote help-~~  
161 ~~seeking, easing transitions into and out of work for people with MHP and other life challenges), Caring for~~  
162 ~~friends/family after a suicide has taken place and supporting family and friends after a suicide, and assuring~~  
163 ~~safe media reporting and messaging in the aftermath of a suicide can reporting by the media in order to prevent~~  
164 ~~suicide contagion (12) and keep people safe. Such a comprehensive approach to suicide prevention to support~~  
165 ~~all people with or without mental health problems is essential and~~ some states, such as Colorado, are  
166 ~~underway planning to implement such a comprehensive a strategy approach to suicide prevention~~ (13).

Comment [FC]: True point but it suggests at least to me there is limited prevention opportunity. Given 22% disclosed suicide intent, perhaps there needs to be more stated here. Idea: suicides can occur with minimal deliberation but many individuals disclose suicidal intent or demonstrate other risk factors that help in identifying at-risk individual who need immediate access to supportive services.

Comment [za19]: updated

Comment [FC]: Wonder if it might be good to move this point down into the paragraph about comprehensive strategies or its own paragraph since it is applicable to those with known and not known MPH. If moved out of this paragraph specific to MPH, and framed more broadly about what all persons need, then attention to a couple of vulnerable populations per earlier comment could be added to this idea.

Comment [za19]: Prefer to keep this as is because we want to want to 'advocate' for better treatment and services for people with MHP.

Comment [FC]: I like the evolution I have seen of the results and discussion to emphasize the difficulties of those without known MHP. I do think it's important as done for the discussion to talk specifically about those with known MPH. But, the two MPH group paragraphs in the discussion seem to tip the balance more toward the MPH group. I suggest weaving into the previous paragraph that

167 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
168 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
169 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
170 estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included  
171 represent 49.6% of the population  
172 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

173 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
174 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
175 interviews with next-of-kin often see greater attributions to mental disorders (14), however many  
176 methodological variations across studies exist (15). It is likely that some people without known MHP in the  
177 current study were experiencing mental health challenges that were unknown, and hence underreported by key  
178 informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad  
179 range of contributing circumstances.

180 Suicide is a growing public health problem ~~with . Effective approaches to prevent the many associated suicide~~  
181 ~~risk factors are available.~~ States and communities can ~~use use data from~~ NVDRS ~~data to better understand their~~  
182 ~~suicide problem~~ and ~~can use~~ resources such as CDC's *Preventing Suicide: a Technical Package of Policies,*  
183 *Programs, and Practices* (12) to ~~better understand their suicide problem and prioritize implement~~ evidence-  
184 based comprehensive suicide prevention ~~to save lives.~~

1 **Short Title:** Vital Signs: ~~Contributing Circumstances to Suicide and Identifying~~ Increasing Trends in State Suicide  
2 Rates ~~and Exploring Suicide's Multiple Contributing Circumstances~~

3 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
4 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

5 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. ~~Mental health problems (MHP)~~  
6 ~~are just one factor contributing to suicide.~~ Examining state-level trends in ~~suicide~~ and ~~other the multiple~~  
7 contributing circumstances ~~to, suicide~~ can inform comprehensive state suicide prevention planning.

8 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
9 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
10 for 50 states and Washington, D.C. Data from the National Violent Death Reporting System (NVDRS), covering  
11 27 states in 2015, were used to examine contributing circumstances among decedents with and without known  
12 ~~MHP~~mental health problems (MHP).

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively.  
15 ~~Among decedents in NVDRS, 54.0% half (54.0%) of decedents did not have a known MHP.~~ Among decedents  
16 with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%),  
17 life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more likely  
18 among those without a known MHP than decedents with MHP, but were common across groups.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

## 24 INTRODUCTION

### 25 BACKGROUND AND PURPOSE

26 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
27 ≥10 years old (1). Between 1999 and 2015, suicide rates increased across ~~both~~ sexes, racial/ethnic groups, and  
28 urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
29 are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
30 for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the  
31 nation more than \$69 billion in direct medical and work loss costs (1).

32 The *National Strategy for Suicide Prevention*(NSSP) (5) calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.

35 Despite the NSSP guidance, suicide prevention efforts largely focus on ~~identifying and treating individuals~~  
36 ~~with clinically-oriented interventions mental health focused on people with mental health~~ problems (MHP) or  
37 ~~providing follow-up care to people who have attempted~~ people who have attempted suicide (6). Other  
38 contributing circumstances include social ~~isolation, relationship problems, and~~ economic problems, access to  
39 lethal means (e.g., substances, firearms, bridges) among people at risk, ~~and~~ poor coping and problem-solving  
40 skills ~~and prior suicide attempts~~ (5). Expanded awareness of these additional circumstances ~~that contributing~~

Comment [FC]: I think some sort of clarification is needed to distinguish from previous two sentences since what is reported here are not data on full examined time period or all 50 states. Tracked an idea but there are likely other ways to clarify.

Comment [zaf9]: Updated

to suicide risk ~~apart from MHP~~, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

**Comment [FC]:** Suggest pulling out the references to tables 2 and 3 since table 1 hasn't been mentioned yet and helps saves on word count. If you want to keep them in, suggest adding "table 1" somewhere into the above paragraph.

**Comment [za19]:** Took the ref to tables out.

**Comment [FC]:** Given attention to this particular at-risk population in the results, made me wonder if some mention of needs of this group should be in the discussion. There are other higher risk groups described below. A consideration could be in the discussion about prevention needs of underserved areas (bottom of page 3) some phrasing could be added about the need for services for higher risk groups, such as those who have served in the military and those who have difficulties, such as MPH, intimate partner problems, have physical health problems, and have financial and legal difficulties. Or on page 4 where "identifying and better supporting people at risk" is stated an e.g. could be added.

**Comment [za19]:** Did not end up adding this as it seemed odd to call out this one population.

85 While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents  
86 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
87 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
88 These differences remained significant in the adjusted models.

89 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
90 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
91 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

92 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
93 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
94 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
95 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

96 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
97 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
98 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
99 were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
100 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
101 the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the  
102 adjusted models. Among those with crises, intimate partner and physical health problems were the most  
103 common types for both groups and did not differ between them.

104 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
105 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
106 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
107 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
108 group were released from psychiatric facilities.

109 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
110 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than 1 in five people in  
111 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 112 Conclusions and Comments

113 From 1999-2016, 44 states saw significant ~~suicide rate increases~~ increases in suicide rates and 25 states  
114 experienced rate increases of more than 30%. Rates increased significantly ~~for among~~ for males, (in 34 states), and  
115 ~~for~~ for females; (in 43 states). This finding is consistent with prior research showing a decreasing gender gap in  
116 male-female suicide rates between 1999-2014 (3). ~~Overall, half of the states experienced substantial increases in~~  
117 ~~suicide rates of more than 30%~~. Additional research into the specific causes of these trends is necessary.  
118 ~~Fortunately in the meantime, data from the 27 states participating in NVDRS NVDRS can shed light on provides~~  
119 ~~insight into the suicide circumstances and circumstances that contributed to recent suicides, and can help~~  
120 ~~states identify prevention priorities. help guide prevention activities.~~

121 ~~Researchers and practitioners~~ Suicidologists regularly state that ‘suicide ‘is not caused by a single factor;’ (5)  
122 however, suicide prevention research and practice ~~prevention practices often focus on is~~ heavily weighted  
123 towards identifying and treating MHP ~~clinically-oriented activities~~ (6). ~~In contrast, t~~ The current study found that  
124 more than half of suicide decedents in NVDRS did not have a known MHP. This group suffered more from  
125 relationship problems ~~issues~~ and other life stressors such as criminal-legal ~~matters~~, housing ~~eviction/loss of~~

**Comment [FC]:** It appears non-MHP is being compared to non-MHP. Tracked what I think the edit is but please double check.

**Comment [za19]:** You are correct. Should be with in the second instances, not without.

126 home, and health problems. They also experienced more and recent/or impending crises which may point to  
 127 suicides. This is particularly noteworthy in light of findings that suggest that took place many suicides and  
 128 attempts occur with minimal deliberation (10). In addition to educating about how to respond to signs or  
 129 disclosures of suicide risk, broader prevention to address non-clinical risks is critical and can include  
 130 strengthening economic supports (e.g., through housing stabilization policies, household financial support);  
 131 teaching coping and problem-solving skills early in life to bolster healthy relationships over the life course; and  
 132 promoting social connectedness to increase one's sense of belonging.

133 The above strategies are also applicable to Among people with MHP who, in the current study struggled more  
 134 with job/financial problems, bereavement issues, and family crises, and who commonly experienced  
 135 arguments/conflicts, intimate partner, and health problems. These findings support a body of literature  
 136 indicating increased vulnerability among people with MHP to socio-economic and health problems (11). In the  
 137 clinical realm, two-thirds of people with MHP had a history of any treatment mental health and/or substance  
 138 abuse treatment and over half 54% were in current treatment when they died. This suggests the need for that  
 139 additional supports for this population are needed to keep them safe. This includes broader broader  
 140 implementation of affordable and effective evidence-based treatment modalities (e.g., such as doctor-patient  
 141 collaborative care, models and cognitive-behavioral therapy). Additionally, greater access to behavioral health  
 142 providers (especially in underserved areas) is needed, as and expanded is expansion of healthcare systems to  
 143 integration of physical and behavioral health that better support suicide prevention and patient safety within  
 144 healthcare systems, especially through care transitions (12).

145 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
 146 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
 147 associated with mental health problems in the first place, and to support people with known MHP to decrease  
 148 their risk of poor social, health, and economic outcomes (11).

149 In addition to the abovementioned strategies, other components of a comprehensive approach Together, these  
 150 results underscore the importance of comprehensive statewide suicide prevention activities that address  
 151 multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports  
 152 (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to  
 153 manage everyday stressors and prevent future relationship problems, especially early in life; promoting social  
 154 connectedness to increase a sense of belongingness and access to informational, emotional, and social support;  
 155 and identifying and better supporting people at risk. Other strategies include: creating protective environments  
 156 by s (e.g., reducing access to lethal means (e.g., medications, firearms) among people at risk, creating  
 157 organizational and workplace policies to encouraging promote employee help-seeking and connectedness;  
 158 easing transitions into and out of work for people with MHP and other life challenges), and zoning to reduce  
 159 alcohol-outlet density; better identifying people at risk; supporting friends/family after a suicide has taken place  
 160 and supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent  
 161 suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive  
 162 approach to suicide prevention (13).

163 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
 164 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
 165 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
 166 estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included  
 167 represent 49.6% of the population  
 168 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

**Comment [FC]:** True point but it suggests at least to me there is limited prevention opportunity. Given 22% disclosed suicide intent, perhaps there needs to be more stated here. Idea: suicides can occur with minimal deliberation but many individuals disclose suicidal intent or demonstrate other risk factors that help in identifying at-risk individual who need immediate access to supportive services.

**Comment [za19]:** updated

**Comment [FC]:** Wonder if it might be good to move this point down into the paragraph about comprehensive strategies or its own paragraph since it is applicable to those with known and not known MPH. If moved out of this paragraph specific to MPH, and framed more broadly about what all persons need, then attention to a couple of vulnerable populations per earlier comment could be added to this idea.

**Comment [za19]:** Prefer to keep this as is because we want to want to 'advocate' for better treatment and services for people with MHP.

**Comment [FC]:** I like the evolution I have seen of the results and discussion to emphasize the difficulties of those without known MHP. I do think it's important as done for the discussion to talk specifically about those with known MPH. But, the two MPH group paragraphs in the discussion seem to tip the balance more toward the MPH group. I suggest weaving into the previous paragraph that

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (14), however many methodological variations across studies exist (15). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem ~~with - Effective approaches to prevent the many associated suicide risk factors are available.~~ States and communities can ~~use use data from NVDRS data to better understand their suicide problem~~ and ~~can use~~ resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to ~~better understand their suicide problem and prioritize implement~~ evidence-based comprehensive suicide prevention ~~to save lives.~~

1 **Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

2 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
3 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

4 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP)  
5 are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing  
6 circumstances can inform comprehensive state suicide prevention planning.

7 **Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six  
8 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
9 for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states  
10 in 2015, were used to examine contributing circumstances among decedents with and without known MHP.

11 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
12 of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively.  
13 Among decedents in 2015 in 27 states, Over half (54.0%) of decedents did not have a known MHP. Among  
14 decedents with circumstance information, several circumstances, including relationship problems/loss (45.1% vs  
15 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more  
16 likely among those without a known MHP than decedents with MHP, but were common across groups.

17 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
18 contributed to suicides among people with and without known MHP.

19 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
20 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
21 friends/family after a suicide occurs.

22 **INTRODUCTION**

23 **BACKGROUND AND PURPOSE**

24 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
25  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and  
26 urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
27 are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
28 for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the  
29 nation more than \$69 billion in direct medical and work loss costs (1).

30 The *National Strategy for Suicide Prevention* (NSSP) (5) calls for a public health approach to suicide prevention  
31 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
32 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
33 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
34 mental health problems (MHP) or providing follow-up care to people who have attempted suicide (6). Other  
35 contributing circumstances include social and economic problems, access to lethal means (e.g., substances,  
36 firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts (5).  
37 Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, and action  
38 to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in  
39 achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing  
40 factors, and provides recommendations for multi-level comprehensive suicide prevention.

**Comment [FC]:** I think some sort of clarification is needed to distinguish from previous two sentences since what is reported here are not data on full examined time period or all 50 states. Tracked an idea but there are likely other ways to clarify.

41 **METHODS**

42 Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children  
 43 are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
 44 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
 45 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
 46 Health Statistics bridged-race population data releases.

47  
 48 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
 49 spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed  
 50 per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
 51 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
 52 are reported in terms of average annual percentage changes (AAPCs).

53  
 54 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known  
 55 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
 56 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and  
 57 Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance  
 58 dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources:  
 59 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
 60 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
 61 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
 62 race/ethnicity.

63 **RESULTS**

64 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
 65 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
 66 Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware)  
 67 to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North  
 68 Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

69  
 70 Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43  
 71 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide  
 72 rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC  
 73 +1.1%) and females (AAPC +2.6%).

74  
 75 Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states.  
 76 While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without  
 77 known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI =  
 78 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had  
 79 significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8).  
 80 Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were  
 81 currently serving, in the U.S. military.

82 While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents  
 83 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
 84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those without known  
 85 MHP. These differences remained significant in the adjusted models.

**Comment [FC]:** Suggest pulling out the references to tables 2 and 3 since table 1 hasn't been mentioned yet and helps saves on word count. If you want to keep them in, suggest adding "table 1" somewhere into the above paragraph.

**Comment [FC]:** Given attention to this particular at-risk population in the results, made me wonder if some mention of needs of this group should be in the discussion. There are other higher risk groups described below. A consideration could be in the discussion about prevention needs of underserved areas (bottom of page 3) some phrasing could be added about the need for services for higher risk groups, such as those who have served in the military and those who have difficulties, such as MPH, intimate partner problems, have physical health problems, and have financial and legal difficulties. Or on page 4 where "identifying and better supporting people at risk" is stated an e.g. could be added.

**Comment [FC]:** It appears non-MHP is being compared to non-MHP. Tracked what I think the edit is but please double check.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

89 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
90 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
91 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
92 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
94 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
95 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
96 were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
97 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
98 the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the  
99 adjusted models. Among those with crises, intimate partner and physical health problems were the most  
100 common types for both groups and did not differ between them.

101 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
102 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
103 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
104 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
105 group were released from psychiatric facilities.

106 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
107 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than 1 in five people in  
108 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 109 Conclusions and Comments

110 From 1999-2016, 44 states saw significant suicide rate increases. Rates increased significantly for males, in 34  
111 states, and for females, in 43 states. This finding is consistent with prior research showing a decreasing gender  
112 gap in male-female suicide rates between 1999-2014 (3). Overall, half of the states experienced substantial  
113 increases in suicide rates of more than 30%. Additional research into the specific causes of these trends is  
114 necessary. Fortunately, data from the 27 states participating in NVDRS can shed light on the circumstances that  
115 contributed to recent suicides, and can help guide prevention activities.

116 Researchers and practitioners regularly state that 'suicide is not caused by a single factor;' however, research  
117 and prevention practices often focus on identifying and treating MHP (6). The current study found that more  
118 than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship  
119 problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.  
120 This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
121 deliberation (10).

122 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
123 half were in current treatment. This suggests that additional supports for this population are needed to keep  
124 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
125 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
126 behavioral health providers in underserved areas is needed, as is expansion of healthcare systems to integrate

**Comment [FC]:** True point but it suggests at least to me there is limited prevention opportunity. Given 22% disclosed suicide intent, perhaps there needs to be more stated here. Idea: suicides can occur with minimal deliberation but many individuals disclose suicidal intent or demonstrate other risk factors that help in identifying at-risk individual who need immediate access to supportive services.

**Comment [FC]:** Wonder if it might be good to move this point down into the paragraph about comprehensive strategies or its own paragraph since it is applicable to those with known and not known MPH. If moved out of this paragraph specific to MPH, and framed more broadly about what all persons need, then attention to a couple of vulnerable populations per earlier comment could be added to this idea.

127 physical and behavioral health that better support suicide prevention and patient safety, especially through care  
128 transitions (11).

129 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
130 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
131 associated with mental health problems in the first place, and to support people with known MHP to decrease  
132 their risk of poor social, health, and economic outcomes (12).

133 Together, these results underscore the importance of comprehensive statewide suicide prevention activities  
134 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
135 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
136 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
137 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
138 emotional, and social support; and identifying and better supporting people at risk. Other strategies include  
139 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
140 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
141 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
142 reporting by the media in order to prevent suicide contagion (11). Some states, such as Colorado, are planning  
143 to implement such a comprehensive approach to suicide prevention (13).

144 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
145 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
146 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
147 estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included  
148 represent 49.6% of the population  
149 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

150 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
151 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
152 interviews with next-of-kin often see greater attributions to mental disorders (14), however many  
153 methodological variations across studies exist (15). It is likely that some people without known MHP in the  
154 current study were experiencing mental health challenges that were unknown, and hence underreported by key  
155 informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad  
156 range of contributing circumstances.

157 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
158 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
159 *Technical Package of Policies, Programs, and Practices* (11) to better understand their suicide problem and  
160 prioritize evidence-based comprehensive suicide prevention.

**Comment [FC]:** I like the evolution I have seen of the results and discussion to emphasize the difficulties of those without known MHP. I do think it's important as done for the discussion to talk specifically about those with known MPH. But, the two MPH group paragraphs in the discussion seem to tip the balance more toward the MPH group. I suggest weaving into the previous paragraph that those with known MHP had other difficulties rather than this being a standalone paragraph.

Also consider if the prevention implication described here is also applicable to those without MPH. There seemed to be a gap in discussion paragraph #2 where similar precipitating circumstances are noted for the non-MPH group but no prevention strategies are presented. Prevention strategies for these types of risk factor could be described either in the non-MPH paragraph or this paragraph could be framed more broadly about the prevention needs of both non-MPH and MPH groups.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts are largely clinically-oriented, focused on treating mental health problems (MHP) and preventing re-attempts (6). Apart from MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes

state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (665)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
85 These differences remained significant in the adjusted models.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

89 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
90 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
91 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
92 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship  
94 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
95 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely  
96 to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or  
97 eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or  
98 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
99 Among all people with crises, intimate partner problems were the most common types and did not differ by  
100 group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and  
101 job/financial problems (15.6% and 16.8%) were commonly experienced and did not differ by group.

102 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
103 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
104 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
105 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
106 group were released from psychiatric facilities.

107 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
108 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
109 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 110 Conclusions and Comments

111 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
112 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
113 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
114 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
115 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
116 circumstances and can help states identify prevention priorities.

117 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention  
118 research and practice is heavily oriented towards downstream treatment of MHP and prevention of reattempts.  
119 Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as  
120 the current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This  
121 group suffered more from relationship problems and other life stressors such as criminal-legal matters,  
122 eviction/loss of home, and recent or impending crises.

123 Similarly, people with MHP also experienced other life stressors such as job/financial, relationship, and/or  
124 physical health problems. These findings point to the need to both prevent the conditions associated with

Comment [HDE(): I would add in the %  
for opioids as it is timely and relevant

Comment [HDE(): I thought they were  
also 2x likely to be released from other  
facility which included drug rehab?

mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known MHP.

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. Over half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention* (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with mental health problems (MHP) (6). Other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts (5). Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

**Comment [HJ]:** Is there a more up-to-date US-based reference than Rosenman 1998?

## 41 METHODS

42 Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children  
 43 are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
 44 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
 45 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
 46 Health Statistics bridged-race population data releases.

48 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
 49 spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed  
 50 per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
 51 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
 52 are reported in terms of average annual percentage changes (AAPCs).

54 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known  
 55 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
 56 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and  
 57 Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance  
 58 dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources:  
 59 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
 60 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
 61 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
 62 race/ethnicity.

## 63 RESULTS

64 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
 65 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
 66 Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware)  
 67 to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North  
 68 Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

70 Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43  
 71 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide  
 72 rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC  
 73 +1.1%) and females (AAPC +2.6%).

75 Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states.  
 76 While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without  
 77 known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI =  
 78 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had  
 79 significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8).  
 80 Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were  
 81 currently serving, in the U.S. military.

82 While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents  
 83 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
 84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those without known  
 85 MHP. These differences remained significant in the adjusted models.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

89 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
90 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
91 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
92 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
94 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
95 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
96 were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
97 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
98 the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the  
99 adjusted models. Among those with crises, intimate partner and physical health problems were the most  
100 common types for both groups and did not differ between them.

101 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
102 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
103 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
104 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
105 group were released from psychiatric facilities.

106 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
107 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempt (10.3% vs. 29.4%). More than 1 in five people in  
108 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 109 Conclusions and Comments

110 From 1999-2016, 44 states saw significant suicide rate increases. Rates increased significantly for males, in 34  
111 states, and for females, in 43 states. This finding is consistent with prior research showing a decreasing gender  
112 gap in male-female suicide rates between 1999-2014 (3). Overall, half of the states experienced substantial  
113 increases in suicide rates of more than 30%. Additional research into the specific causes of these trends is  
114 necessary. Fortunately, data from the 27 states participating in NVDRS can shed light on the circumstances that  
115 contributed to recent suicides, and can help guide prevention activities.

116 Researchers and practitioners regularly state that 'suicide is not caused by a single factor;' however, research  
117 and prevention practices, almost solely, focus on identifying and treating MHP. The current study found that  
118 more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship  
119 problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.  
120 This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
121 deliberation (10).

122 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
123 half were in current treatment. This suggests that additional supports for this population are needed to keep  
124 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
125 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
126 behavioral health providers in underserved areas is needed, as is expansion of healthcare systems to integrate

Comment [HJ]: Add citations to support this statement.

Comment [za19]: Alex-- add Zalsman again? Don't have room for another ref.

127 physical and behavioral health that better support suicide prevention and patient safety, especially through care  
128 transitions (11).

129 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
130 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
131 associated with mental health problems in the first place, and to support people with known MHP to decrease  
132 their risk of poor social, health, and economic outcomes (12).

133 Together, these results underscore the importance of comprehensive statewide suicide prevention activities  
134 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
135 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
136 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
137 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
138 emotional, and social support; and identifying and better supporting people at risk. Other strategies include  
139 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
140 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
141 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
142 reporting by the media in order to prevent suicide contagion (11). Some states, such as Colorado, are planning  
143 to implement such a comprehensive approach to suicide prevention (13).

144 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
145 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
146 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
147 estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included  
148 represent 49.6% of the population  
149 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

150 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
151 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
152 interviews with next-of-kin often see greater attributions to mental disorders (14), however many  
153 methodological variations across studies exist (15). It is likely that some people without known MHP in the  
154 current study were experiencing mental health challenges that were unknown, and hence underreported by key  
155 informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad  
156 range of contributing circumstances.

157 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
158 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
159 *Technical Package of Policies, Programs, and Practices* (11) to better understand their suicide problem and  
160 prioritize evidence-based comprehensive suicide prevention.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known MHP.

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. Over half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people ≥10 years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention* (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with mental health problems (MHP) (6). Other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts (5). Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

**Comment [HJ]:** Is there a more up-to-date US-based reference than Rosenman 1998?

**Comment [za19]:** Alex, what about the Zalsman systematic review? If you look at all the treatment strategies they appear to outweigh any other strategies and within the limiting access to lethal means, many of the studies are international.  
1. Zalsman, G., et al., *Suicide prevention strategies revisited: 10-year systematic review*. The Lancet Psychiatry, 2016. 3(7): p. 646-659.

41 **METHODS**

42 Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children  
 43 are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
 44 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
 45 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
 46 Health Statistics bridged-race population data releases.

48 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
 49 spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed  
 50 per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
 51 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
 52 are reported in terms of average annual percentage changes (AAPCs).

54 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known  
 55 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
 56 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and  
 57 Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance  
 58 dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources:  
 59 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
 60 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
 61 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
 62 race/ethnicity.

63 **RESULTS**

64 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
 65 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
 66 Nevada (with the 9<sup>th</sup> highest current suicide rate which consistently has one of the highest suicide rates), with  
 67 absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates  
 68 ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states  
 69 (Table 1, Figure 1).

71 Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43  
 72 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide  
 73 rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC  
 74 +1.1%) and females (AAPC +2.6%).

76 Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states.  
 77 While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without  
 78 known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI =  
 79 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.4; 95% CI range: 1.0-1.3) – (1.36-2.0) (63.1). Suicide  
 80 decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted  
 81 odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with  
 82 MHP, respectively, ever served, or were currently serving, in the U.S. military.

83 While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents  
 84 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
 85 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those without known  
 86 MHP. These differences remained significant in the adjusted models.

**Comment [za9]:** SK, TS, Opinions as to whether this should stay here or be moved to limitations? I'd prefer to keep it here but realize it may not be conventional.

**Comment [ST]:** I agree with keeping it here.

**Comment [HJ]:** Per Table 2, the range in ORs for non-white racial/ethnic groups is 1.2 to 2.0. Please confirm.

**Comment [za9]:** KY, KF, Jeff looks to be correct.

**Comment [HJ]:** Per Table 2, the range in the lower bound of the 95% CIs for non-white racial/ethnic groups is 1.0 (Hispanic) to 1.6 (AI/AN).

**Comment [za9]:** KF, KY, TS--This looks correct to me. Jeff was looking at the data a little differently. For the lower limits here (LL), he took the smallest and largest numbers across all LL CIs and then did the same for upper limits. I'm guessing you guys have done this before and it's accepted?

**Comment [ST]:** I see how this could be confusing. I'm thinking that we could drop the CI range here. The reader can find them in the table.

**Comment [HJ]:** Per Table 2, the range in the upper bound of the 95% CIs for non-white racial/ethnic groups is 1.3 (Hispanic) to 3.1 (Other). Please confirm.

**Comment [za9]:** KF, KY. Actually this looks like a typo. Should be 1.6-2.6—See above comment about Jeff's interpretation.

**Comment [FKA]:** I see how Jeff is thinking about this – have made changes in line with this but talked w Keming and we are also ok w cutting it if that's better. Your call.

87 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
88 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
89 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

90 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
91 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
92 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
93 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

94 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
95 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
96 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
97 were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
98 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
99 the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the  
100 adjusted models. Among those with crises, intimate partner and physical health problems were the most  
101 common types for both groups and did not differ between them.

102 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
103 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
104 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
105 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
106 group were released from psychiatric facilities.

107 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
108 suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in  
109 five people in both groups disclosed suicide intent (22.4% vs. 24.5%).

## 110 Conclusions and Comments

111 From 1999-2016, 44 states saw significant suicide rate increases. Rates increased significantly for males, in 34  
112 states, and for females, in 43 states. This finding is consistent with prior research showing a decreasing gender  
113 gap in male-female suicide rates between 1999-2014 (3). Overall, half of the states experienced substantial  
114 increases in suicide rates of more than 30%. Additional research into the specific causes of these trends is  
115 necessary. Fortunately, data from the 27 states participating in NVDRS can shed light on the circumstances that  
116 contributed to recent suicides, and can help guide prevention activities.

117 Researchers and practitioners regularly state it is common parlance in the field that 'suicide is not caused by a  
118 single factor;' however, suicide research and prevention practices, almost solely, largely focus on identifying and  
119 treating MHP. The current study found that more than half of suicide decedents in NVDRS did not have a known  
120 MHP. This group suffered more relationship problems and life stressors such as criminal-legal matters,  
121 eviction/loss of home, and recent or impending crises. This is particularly noteworthy in light of findings that  
122 suggest many suicides and attempts occur with minimal deliberation (10).

123 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
124 half were in current treatment. This suggests that additional supports for this population are needed to keep  
125 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
126 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
127 behavioral health providers in underserved areas is needed, as is expansion of healthcare systems to integrate

Comment [HJ(): Any comment on substance causes of death?

Comment [za9]: TS--No room ☹

Comment [ST(): I agree about the lack of room. We also don't address this in prevention. Let's see if other reviewers raise it.

Comment [HJ(): Might be better to report as: 23.0% vs. 40.8%

Comment [HJ(): Might be better to report as: 29.4% vs. 10.3%

Comment [za9]: KF, KY, TS--I tried to preserve aOR's!! Thoughts?

Comment [ST(): I see his point. The % differences are more compelling. This would also make the paragraph more consistent since the last sentence used %'s.

Comment [FKA(): I'm ok with that because these are the ones where we're speaking about the group that has significantly lower odds. My thoughts are the same in general about keeping vs. excluding odds ratios, but willing to be flexible (I think we've got to be in this process!).

Comment [HJ(): Add citations to support this statement.

Comment [za9]: Alex-- add Zalsman again? Don't have room for another ref.

Comment [HJ(): Any comment that the top ranking states are rural and mainly in the Northwest: MT, AK, WY, UT

Comment [za9]: Unfortunately we can't accommodate the added text.

128 physical and behavioral health that better support suicide prevention and patient safety, especially through care  
129 transitions (11).

130 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
131 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
132 associated with mental health problems in the first place, and to support people with known MHP to decrease  
133 their risk of poor social, health, and economic outcomes (12).

134 Together, these results underscore the importance of comprehensive statewide suicide prevention activities  
135 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
136 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
137 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
138 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
139 emotional, and social support; and identifying and better supporting people at risk. Other strategies include  
140 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
141 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
142 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
143 reporting by the media in order to prevent suicide contagion (11). Some states, such as Colorado, are planning  
144 to implement such a comprehensive approach to suicide prevention (13).

145 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
146 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
147 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
148 estimated rate trends upward). **Second**, NVDRS is not yet nationally representative; the 27 states included  
149 represent 49.6% of the population

150 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

151 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
152 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
153 interviews with next-of-kin often see greater attributions to mental disorders (14), however many  
154 methodological variations across studies exist (15). It is likely that some people without known MHP in the  
155 current study were experiencing mental health challenges that were unknown, and hence underreported by key  
156 informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad  
157 range of contributing circumstances.

158 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
159 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
160 *Technical Package of Policies, Programs, and Practices* (11) to better understand their suicide problem and  
161 prioritize evidence-based comprehensive suicide prevention.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known MHP.

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. Over half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention* (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with mental health problems (MHP) (6). Other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts (5). Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

**Comment [HJ]:** Is there a more up-to-date US-based reference than Rosenman 1998?

**Comment [za19]:** Alex, what about the Zalsman systematic review? If you look at all the treatment strategies they appear to outweigh any other strategies and within the limiting access to lethal means, many of the studies are international.

41 **METHODS**

42 Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children  
 43 are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
 44 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
 45 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
 46 Health Statistics bridged-race population data releases.

47  
 48 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
 49 spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed  
 50 per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
 51 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
 52 are reported in terms of average annual percentage changes (AAPCs).

53  
 54 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known  
 55 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
 56 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and  
 57 Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance  
 58 dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources:  
 59 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
 60 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
 61 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
 62 race/ethnicity.

63 **RESULTS**

64 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
 65 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
 66 Nevada (with the 9<sup>th</sup> highest current suicide rate which consistently has one of the highest suicide rates), with  
 67 absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates  
 68 ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states  
 69 (Table 1, Figure 1).

70  
 71 Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43  
 72 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide  
 73 rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC  
 74 +1.1%) and females (AAPC +2.6%).

75  
 76 Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states.  
 77 While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without  
 78 known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI =  
 79 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.4; 95% CI range 1.0-1.3) – 1.6-2.9 (6). Suicide decedents  
 80 without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio  
 81 aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP,  
 82 respectively, ever served, or were currently serving, in the U.S. military.

83 While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents  
 84 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
 85 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those without known  
 86 MHP. These differences remained significant in the adjusted models.

**Comment [za9]:** SK, TS, Opinions as to whether this should stay here or be moved to limitations? I'd prefer to keep it here but realize it may not be conventional.

**Comment [HJ]:** Per Table 2, the range in ORs for non-white racial/ethnic groups is 1.2 to 2.0. Please confirm.

**Comment [za9]:** KY, KF, Jeff looks to be correct.

**Comment [HJ]:** Per Table 2, the range in the lower bound of the 95% CIs for non-white racial/ethnic groups is 1.0 (Hispanic) to 1.6 (AI/AN).

**Comment [za9]:** KF, KY, TS—This looks correct to me. Jeff was looking at the data a little differently. For the lower limits here (LL), he took the smallest and largest numbers across all LL CIs and then did the same for upper limits. I'm guessing you guys have done this before and it's accepted?

**Comment [HJ]:** Per Table 2, the range in the upper bound of the 95% CIs for non-white racial/ethnic groups is 1.3 (Hispanic) to 3.1 (Other). Please confirm.

**Comment [za9]:** KF, KY. Actually this looks like a typo. Should be 1.6-2.6—See above comment about Jeff's interpretation.

87 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
88 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
89 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

90 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
91 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
92 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
93 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

94 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
95 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
96 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
97 were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
98 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
99 the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the  
100 adjusted models. Among those with crises, intimate partner and physical health problems were the most  
101 common types for both groups and did not differ between them.

102 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
103 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
104 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
105 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
106 group were released from psychiatric facilities.

107 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
108 suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in  
109 five people in both groups disclosed suicide intent (22.4% vs. 24.5%).

## 110 Conclusions and Comments

111 From 1999-2016, 44 states saw significant suicide rate increases. Rates increased significantly for males, in 34  
112 states, and for females, in 43 states. This finding is consistent with prior research showing a decreasing gender  
113 gap in male-female suicide rates between 1999-2014 (3). Overall, half of the states experienced substantial  
114 increases in suicide rates of more than 30%. Additional research into the specific causes of these trends is  
115 necessary. Fortunately, data from the 27 states participating in NVDRS can shed light on the circumstances that  
116 contributed to recent suicides, and can help guide prevention activities.

117 Researchers and practitioners regularly state it is common parlance in the field that 'suicide is not caused by a  
118 single factor,' however, suicide research and prevention practices, almost solely, largely focus on identifying and  
119 treating MHP. The current study found that more than half of suicide decedents in NVDRS did not have a known  
120 MHP. This group suffered more relationship problems and life stressors such as criminal-legal matters,  
121 eviction/loss of home, and recent or impending crises. This is particularly noteworthy in light of findings that  
122 suggest many suicides and attempts occur with minimal deliberation (10).

123 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
124 half were in current treatment. This suggests that additional supports for this population are needed to keep  
125 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
126 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
127 behavioral health providers in underserved areas is needed, as is expansion of healthcare systems to integrate

Comment [HJ]: Any comment on substance causes of death?

Comment [za9]: TS--No room ☹

Comment [HJ]: Might be better to report as: 23.0% vs. 40.8%

Comment [HJ]: Might be better to report as: 29.4% vs. 10.3%

Comment [HJ]: Any comment that the top ranking states are rural and mainly in the Northwest: MT, AK, WY, UT

Comment [za9]: Unfortunately we can't accommodate the added text.

128 physical and behavioral health that better support suicide prevention and patient safety, especially through care  
129 transitions (11).

130 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
131 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
132 associated with mental health problems in the first place, and to support people with known MHP to decrease  
133 their risk of poor social, health, and economic outcomes (12).

134 Together, these results underscore the importance of comprehensive statewide suicide prevention activities  
135 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
136 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
137 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
138 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
139 emotional, and social support; and identifying and better supporting people at risk. Other strategies include  
140 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
141 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
142 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
143 reporting by the media in order to prevent suicide contagion (11). Some states, such as Colorado, are planning  
144 to implement such a comprehensive approach to suicide prevention (13).

145 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
146 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
147 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
148 estimated rate trends upward). **Second**, NVDRS is not yet nationally representative; the 27 states included  
149 represent 49.6% of the population

150 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

151 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
152 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
153 interviews with next-of-kin often see greater attributions to mental disorders (14), however many  
154 methodological variations across studies exist (15). It is likely that some people without known MHP in the  
155 current study were experiencing mental health challenges that were unknown, and hence underreported by key  
156 informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad  
157 range of contributing circumstances.

158 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
159 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
160 *Technical Package of Policies, Programs, and Practices* (11) to better understand their suicide problem and  
161 prioritize evidence-based comprehensive suicide prevention.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. (D.C.). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known MHP.

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old [1]. Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs [1].

The *National Strategy for Suicide Prevention* (NSSP) [5] calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific

**Comment [HJ]:** Is there a more up-to-date US-based reference than Rosenman 1998?

40 trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level  
41 comprehensive suicide prevention.

## 42 METHODS

43 Suicide rates were analyzed for people aged ≥10 years only, as attributions of suicidal intent in younger children  
44 are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
45 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
46 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
47 Health Statistics bridged-race population data releases.

48  
49 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
50 spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed  
51 per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
52 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
53 are reported in terms of average annual percentage changes (AAPCs).

54  
55 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents ≥10 years, with and without known  
56 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
57 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and  
58 Statistical Manual of Mental Disorders, Fifth Edition [9], with the exception of alcohol and other substance  
59 dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources:  
60 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
61 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
62 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
63 race/ethnicity.

## 64 RESULTS

65 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
66 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
67 Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1  
68 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota),  
69 with increases of more than 30% observed in 25 states (Table 1, Figure 1).

70  
71 Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43  
72 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide  
73 rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC  
74 +1.1%) and females (AAPC +2.6%).

75  
76 Suicide decedents in 27 states without known MHP (N=11,039) were compared to those with MHP (N=9,407).  
77 While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without  
78 known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI =  
79 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.1; 95% CI range 1.0-1.3 – 1.6-2.0). Suicide decedents  
80 without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio  
81 aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP,  
82 respectively, ever served, or were currently serving, in the U.S. military.

83 While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents  
84 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

**Comment [HJ]:** And consistently high rates since 1999-2001.

**Comment [HJ]:** Per Table 2, the range in ORs for non-white racial/ethnic groups is 1.2 to 2.0. Please confirm.

**Comment [HJ]:** Per Table 2, the range in the lower bound of the 95% CIs for non-white racial/ethnic groups is 1.0 (Hispanic) to 1.6 (AI/AN).

**Comment [HJ]:** Per Table 2, the range in the upper bound of the 95% CIs for non-white racial/ethnic groups is 1.3 (Hispanic) to 3.1 (Other). Please confirm.

85 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those without known  
86 MHP. These differences remained significant in the adjusted models.

87 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
88 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
89 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

90 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
91 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
92 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
93 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

94 Decedents without known MHP versus those with known MHP, had a significantly greater likelihood of any  
95 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
96 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
97 were also more likely to have experienced other any life stressors (54.2% vs 49.7%), such as criminal-legal  
98 problems (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a  
99 crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained  
100 significant in the adjusted models. Among those with crises, intimate partner and physical health problems were  
101 the most common types for both groups and did not differ between them.

102 Decedents without known MHP had significantly lower odds of recent release (aOR=0.5 95% CI 0.4-0.5) from  
103 any institution (aOR=0.5, 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were  
104 significantly more likely to be released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%)  
105 than those with a known MHP. Among decedents with known MHP who were recently released from an  
106 institution (10.2%), 46.7% of this group were released from psychiatric facilities.

107 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
108 suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in  
109 five people in both groups disclosed suicide intent (22.4% vs. 24.5%).

## 110 Conclusions and Comments

111 From 1999-2016, 44 states saw significant suicide rate increases. Rates increased significantly for males, in 34  
112 states, and for females, in 43 states. This finding is consistent with prior research showing a decreasing gender  
113 gap in male-female suicide rates between 1999-2014 [3]. Overall, half of the states experienced substantial  
114 increases in suicide rates of more than 30%. Additional research into the specific causes of these trends is  
115 necessary. Fortunately, data from the 27 states participating in NVDRS can shed light on the circumstances that  
116 contributed to recent suicides, and can help guide prevention activities.

117 Researchers and practitioners regularly state that suicide is not caused by a single factor; however, the focus of  
118 suicide research and prevention practices, almost solely, focus on identify and treating MHP. The current study  
119 found that more than half of suicide decedents in NVDRS did not have a known MHP. This group suffered more  
120 relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or  
121 impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts  
122 occur with minimal deliberation [10].

123 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
124 half were in current treatment. This suggests that additional supports for this population are needed to keep  
125 them safe. This includes broader implementation of affordable and effective treatment modalities such as

Comment [HJ()]: Any comment on substance causes of death?

Comment [HJ()]: Might be better to report as: 23.0% vs. 40.8%

Comment [HJ()]: Might be better to report as: 29.4% vs. 10.3%

Comment [HJ()]: Add citations to support this statement.

126 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
127 behavioral health providers, ~~especially in underserved~~ areas is needed, as is expansion of healthcare systems  
128 ~~needed that to~~ integrate physical and behavioral health ~~and that~~ better support suicide prevention and patient  
129 safety, especially through care transitions [11].

130 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
131 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
132 associated with mental health problems in the first place, ~~and the need to~~ support people with known MHP to  
133 decrease their risk of poor social, health, and economic outcomes [12].

134 ~~Together,~~ these results, ~~together,~~ underscore the importance of comprehensive statewide suicide prevention  
135 activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
136 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
137 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
138 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
139 emotional, and social support; ~~and~~ identifying and better supporting people at risk. Other strategies include  
140 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
141 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
142 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
143 reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning  
144 ~~and implementing to implement~~ such a comprehensive approach to suicide prevention [13].

145 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
146 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
147 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
148 estimated rate trends upward). ~~Second,~~ NVDRS is not yet nationally representative; the 27 states included  
149 represent 49.6% of the population  
150 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

151 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
152 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
153 interviews with next-of-kin often see greater attributions to mental disorders [14], however many  
154 methodological variations across studies exist [15]. It is likely that some people without known MHP in the  
155 current study were experiencing mental health challenges that were unknown, and hence ~~under~~reported by key  
156 informants. However, any lack of awareness of decedent MHP suggests, ~~even further,~~ the importance of  
157 addressing the broad range of contributing circumstances.

158 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
159 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
160 *Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and  
161 prioritize evidence-based comprehensive suicide prevention.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known MHP.

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a known MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old [1]. Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs [1].

The *National Strategy for Suicide Prevention (NSSP)* [5] calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific

trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9], with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by suffocation

### 3.27.18 MMWR for e-clearance

85 (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those without known MHP. These differences remained  
86 significant in the adjusted models.

87 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
88 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
89 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

90 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
91 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
92 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
93 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

94 Decedents without known MHP versus those with known MHP, had a greater likelihood of any relationship  
95 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
96 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They were also more likely  
97 to have experienced other life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%) or  
98 eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within the preceding or  
99 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
100 Among those with crises, intimate partner and physical health problems were the most common types for both  
101 groups and did not differ between them.

102 Decedents without known MHP had significantly lower odds of recent release (aOR=0.5 95% CI (0.4-0.5) from  
103 any institution, but among those who were recently released (5.1%), they were significantly more likely to be  
104 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
105 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
106 group were released from psychiatric facilities.

107 Decedents without known MHP, compared to those with MHP, were less likely to have a history of suicidal  
108 ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). More than 1 in five  
109 people in both groups disclosed suicide intent (22.4% vs. 24.5%).

### 110 **Conclusions and Comments**

111 From 1999-2016, 44 states saw significant suicide rate increases. Rates increased significantly for males, in 34  
112 states, and for females, in 43 states. This finding is consistent with prior research showing a decreasing gender  
113 gap in male-female suicide rates between 1999-2014 [3]. Overall, half of the states experienced substantial  
114 increases in suicide rates of more than 30%. Additional research into the specific causes of these trends is  
115 necessary. Fortunately, data from the states participating in NVDRS can shed light on the circumstances that  
116 contributed to recent suicides, and can help guide prevention activities.

117 Researchers and practitioners regularly state that suicide is not caused by a single factor, however, the focus of  
118 suicide research and prevention practices, almost solely, focus on identify and treating MHP. The current study  
119 found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more  
120 relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or  
121 impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts  
122 occur with minimal deliberation [10].

123 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
124 half were in current treatment. This suggests that additional supports for this population are needed to keep  
125 them safe. This includes broader implementation of affordable and effective treatment modalities such as

126 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
127 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems  
128 needed that integrate physical and behavioral health and that better support suicide prevention and patient  
129 safety, especially through care transitions [11].

130 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
131 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
132 associated with mental health problems in the first place and the need to support people with known MHP to  
133 decrease their risk of poor social, health, and economic outcomes [12].

134 These results, together, underscore the importance of comprehensive statewide suicide prevention activities  
135 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
136 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
137 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
138 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
139 emotional, and social support, and identifying and better supporting people at risk. Other strategies include  
140 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
141 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
142 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
143 reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning  
144 and implementing such a comprehensive approach to suicide prevention [13].

145 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
146 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
147 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
148 estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included  
149 represent 49.6% of the population  
150 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

151 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
152 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
153 interviews with next-of-kin often see greater attributions to mental disorders [14], however many  
154 methodological variations across studies exist [15]. It is likely that some people without known MHP in the  
155 current study were experiencing mental health challenges that were unknown, and hence unreported by key  
156 informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of  
157 addressing the broad range of contributing circumstances.

158 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
159 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
160 *Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and  
161 prioritize evidence-based comprehensive suicide prevention.

1 **Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

2 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
3 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

4 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP)  
5 are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing  
6 circumstances can inform comprehensive state suicide prevention planning.

7 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
8 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
9 for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states  
10 in 2015, were used to examine contributing circumstances among decedents with and without known MHP.

11 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
12 of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively.

13 Among decedents in 2015 in 27 states, Over half (54.0%) of decedents did not have a known MHP. Among  
14 decedents with circumstance information, several circumstances, including relationship problems/loss (45.1% vs  
15 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more  
16 likely among those without a known MHP than decedents with MHP, but were common across groups.

17 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
18 contributed to suicides among people with and without known MHP.

19 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
20 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
21 friends/family after a suicide occurs.

22 **INTRODUCTION**

23 **BACKGROUND AND PURPOSE**

24 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
25 ≥10 years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and  
26 urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
27 are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
28 for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the  
29 nation more than \$69 billion in direct medical and work loss costs (1).

30 The *National Strategy for Suicide Prevention*(NSSP) (5) calls for a public health approach to suicide prevention  
31 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
32 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
33 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
34 mental health problems (MHP) or providing follow-up care to people who have attempted suicide (6). Other  
35 contributing circumstances include social and economic problems, access to lethal means (e.g., substances,  
36 firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts (5).  
37 Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, and action  
38 to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in  
39 achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing  
40 factors, and provides recommendations for multi-level comprehensive suicide prevention.

**Comment [FC]:** I think some sort of clarification is needed to distinguish from previous two sentences since what is reported here are not data on full examined time period or all 50 states. Tracked an idea but there are likely other ways to clarify.

**Comment [aig0]:** Suggest change in wording here for flow: In 2015, more than half (54.0%) of decedents in 27 states did not have..... (just suggestion not required change)

**Comment [RM]:** Is it prevent suicide RISK before it occurs? Or prevent suicide? Haven't seen it phrased that way before.

41 **METHODS**

42 Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children  
 43 are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
 44 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
 45 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
 46 Health Statistics bridged-race population data releases.

47  
 48 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
 49 spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed  
 50 per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
 51 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
 52 are reported in terms of average annual percentage changes (AAPCs).

53  
 54 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known  
 55 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
 56 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and  
 57 Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance  
 58 dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources:  
 59 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
 60 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
 61 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
 62 race/ethnicity.

63 **RESULTS**

64 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
 65 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
 66 Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware)  
 67 to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North  
 68 Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

69  
 70 Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43  
 71 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide  
 72 rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC  
 73 +1.1%) and females (AAPC +2.6%).

74  
 75 Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states.  
 76 While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without  
 77 known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI =  
 78 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had  
 79 significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8).  
 80 Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were  
 81 currently serving, in the U.S. military.

82 While use of firearms were was the most common method of suicide overall (48.5%) and for both groups,  
 83 decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
 84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those without known  
 85 MHP. These differences remained significant in the adjusted models.

**Comment [aig0]:** This is unclear to me. Do you mean that assigning intent in a younger person is variable or difficult to determine? Not sure variable is the correct word

**Comment [FC]:** Suggest pulling out the references to tables 2 and 3 since table 1 hasn't been mentioned yet and helps saves on word count. If you want to keep them in, suggest adding "table 1" somewhere into the above paragraph.

**Comment [FC]:** Given attention to this particular at-risk population in the results, made me wonder if some mention of needs of this group should be in the discussion. There are other higher risk groups described below. A consideration could be in the discussion about prevention needs of underserved areas (bottom of page 3) some phrasing could be added about the need for services for higher risk groups, such as those who have served in the military and those who have difficulties, such as MPH, intimate partner problems, have physical health problems, and have financial and legal difficulties. Or on page 4 where "identifying and better supporting people at risk" is stated an e.g. could be added.

**Comment [FC]:** It appears non-MHP is being compared to non-MHP. Tracked what I think the edit is but please double check.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

89 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
90 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
91 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
92 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
94 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
95 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
96 also were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal  
97 problems (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a  
98 crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained  
99 significant in the adjusted models. Among those with crises, intimate partner and physical health problems were  
100 the most common types for both groups and did not differ between them.

101 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
102 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
103 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
104 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
105 group were released from psychiatric facilities.

106 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
107 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than 1 in five people in  
108 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 109 Conclusions and Comments

110 From 1999-2016, 44 states saw significant suicide rate increases. Rates increased significantly for males, in 34  
111 states, and for females, in 43 states. This finding is consistent with prior research showing a decreasing gender  
112 gap in male-female suicide rates between 1999-2014 (3). Overall, half of the states experienced substantial  
113 increases in suicide rates of more than 30%. Additional research into the specific causes of these trends is  
114 necessary. Fortunately, data from the 27 states participating in NVDRS can shed light on the circumstances that  
115 contributed to recent suicides, and can help guide prevention activities.

116 Researchers and practitioners regularly state that 'suicide is not caused by a single factor,' however, research  
117 and prevention practices often focus on identifying and treating MHP (6). The current study found that more  
118 than half of suicide decedents in NVDRS did not have a known MHP. This group suffered more relationship  
119 problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.  
120 This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
121 deliberation (10).

122 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
123 half were in current treatment. This suggests that additional supports for this population are needed to keep  
124 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
125 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
126 behavioral health providers in underserved areas is needed, as is expansion of healthcare systems to integrate

**Comment [aig0]:** This statement needs a reference. Not sure if reference 6 covers both parts of the sentence.

**Comment [FC():** True point but it suggests at least to me there is limited prevention opportunity. Given 22% disclosed suicide intent, perhaps there needs to be more stated here. Idea: suicides can occur with minimal deliberation but many individuals disclose suicidal intent or demonstrate other risk factors that help in identifying at-risk individual who need immediate access to supportive services.

**Comment [FC():** Wonder if it might be good to move this point down into the paragraph about comprehensive strategies or its own paragraph since it is applicable to those with known and not known MPH. If moved out of this paragraph specific to MPH, and framed more broadly about what all persons need, then attention to a couple of vulnerable populations per earlier comment could be added to this idea.

127 physical and behavioral health that better support suicide prevention and patient safety, especially through care  
128 transitions (11).

129 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
130 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
131 associated with mental health problems in the first place, and to support people with known MHP to decrease  
132 their risk of poor social, health, and economic outcomes (12).

133 Together, these results underscore the importance of comprehensive statewide suicide prevention activities  
134 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
135 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
136 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
137 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
138 emotional, and social support; and identifying and better supporting people at risk. Other strategies include  
139 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
140 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
141 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
142 reporting by the media in order to prevent suicide contagion (11). Some states, such as Colorado, are planning  
143 to implement such a comprehensive approach to suicide prevention (13).

144 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
145 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
146 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
147 estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included  
148 represent 49.6% of the population  
149 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

150 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
151 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
152 interviews with next-of-kin often see greater attributions to mental disorders (14), however many  
153 methodological variations across studies exist (15). It is likely that some people without known MHP in the  
154 current study were experiencing mental health challenges that were unknown, and hence underreported by key  
155 informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad  
156 range of contributing circumstances.

157 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
158 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
159 *Technical Package of Policies, Programs, and Practices* (11) to better understand their suicide problem and  
160 prioritize evidence-based comprehensive suicide prevention.

**Comment [FC]:** I like the evolution I have seen of the results and discussion to emphasize the difficulties of those without known MHP. I do think it's important as done for the discussion to talk specifically about those with known MPH. But, the two MPH group paragraphs in the discussion seem to tip the balance more toward the MPH group. I suggest weaving into the previous paragraph that those with known MHP had other difficulties rather than this being a standalone paragraph.

Also consider if the prevention implication described here is also applicable to those without MPH. There seemed to be a gap in discussion paragraph #2 where similar precipitating circumstances are noted for the non-MPH group but no prevention strategies are presented. Prevention strategies for these types of risk factor could be described either in the non-MPH paragraph or this paragraph could be framed more broadly about the prevention needs of both non-MPH and MPH groups.

209 **Word Count:** 1858/1800

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known MHP.

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. Over half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention* (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with mental health problems (MHP) or providing follow-up care to people who have attempted suicide (6). Other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts (5). Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## 41 METHODS

42 Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children  
 43 are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
 44 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
 45 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
 46 Health Statistics bridged-race population data releases.

48 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
 49 spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed  
 50 per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
 51 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
 52 are reported in terms of average annual percentage changes (AAPCs).

54 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known  
 55 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
 56 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and  
 57 Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance  
 58 dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources:  
 59 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
 60 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
 61 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
 62 race/ethnicity.

## 63 RESULTS

64 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
 65 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
 66 Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware)  
 67 to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North  
 68 Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

70 Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43  
 71 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide  
 72 rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC  
 73 +1.1%) and females (AAPC +2.6%).

75 Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states.  
 76 While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without  
 77 known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI =  
 78 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had  
 79 significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8).  
 80 Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were  
 81 currently serving, in the U.S. military.

82 While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents  
 83 without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by  
 84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those without known  
 85 MHP. These differences remained significant in the adjusted models.

Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95% CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available circumstances information (Table 3). People without known MHP were less likely to have any substance abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without known MHP versus those with known MHP had significantly greater likelihood of any relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models. Among those with crises, intimate partner and physical health problems were the most common types for both groups and did not differ between them.

Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5, 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this group were released from psychiatric facilities.

Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than 1 in five people in both groups disclosed suicide intent (22.4% vs. 24.5%).

## Conclusions and Comments

From 1999-2016, 44 states saw significant suicide rate increases. Rates increased significantly for males, in 34 states, and for females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-female suicide rates between 1999-2014 (3). Overall, half of the states experienced substantial increases in suicide rates of more than 30%. Additional research into the specific causes of these trends is necessary. Fortunately, data from the 27 states participating in NVDRS can shed light on the circumstances that contributed to recent suicides, and can help guide prevention activities.

Researchers and practitioners regularly state that ‘suicide is not caused by a single factor;’ however, research and prevention practices often focus on identifying and treating MHP (6). The current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal deliberation (10).

Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over half were in current treatment. This suggests that additional supports for this population are needed to keep them safe. This includes broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems to integrate

127 physical and behavioral health that better support suicide prevention and patient safety, especially through care  
128 transitions (11).

129 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
130 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
131 associated with mental health problems in the first place, and to support people with known MHP to decrease  
132 their risk of poor social, health, and economic outcomes (12).

133 Together, these results underscore the importance of comprehensive statewide suicide prevention activities  
134 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
135 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
136 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
137 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
138 emotional, and social support; and identifying and better supporting people at risk. Other strategies include  
139 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
140 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
141 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
142 reporting by the media in order to prevent suicide contagion (11). Some states, such as Colorado, are planning  
143 to implement such a comprehensive approach to suicide prevention (13).

144 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
145 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
146 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
147 estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included  
148 represent 49.6% of the population  
149 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

150 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
151 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
152 interviews with next-of-kin often see greater attributions to mental disorders (14), however many  
153 methodological variations across studies exist (15). It is likely that some people without known MHP in the  
154 current study were experiencing mental health challenges that were unknown, and hence underreported by key  
155 informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad  
156 range of contributing circumstances.

157 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
158 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
159 *Technical Package of Policies, Programs, and Practices* (11) to better understand their suicide problem and  
160 prioritize evidence-based comprehensive suicide prevention.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

\* Rates are age-adjusted to the U.S. year 2000 standard.

† Model-estimated average annual percentage change (AAPC) based on all reporting periods; p-value indicates statistical significance of trend; n/s indicates trend not significant.

§ Current state rank (50 states and the District of Columbia) is for the reporting period 2014 – 2016. Ranks are from highest rate (1) to lowest rate (51). Differences between ranks do not necessarily imply a statistically significant difference.

¶ Overall rate change is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest increase (1) to largest decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

\*\* Overall percent change in rates is between the first (1999 – 2001) and last (2014 – 2016) reporting periods. Ranks are from largest percentage increase (1) to largest percentage decrease (51). Differences between ranks do not necessarily imply a statistically significant difference.

†† Rate based on < 20 suicides.

§§ Percentage of injury deaths for which intent was not determined exceeded 20% for both the first and last periods and might have contributed to lower reported rates.

¶¶ Percentage of injury deaths for which intent was not determined declined notably between the first and last periods and might have contributed to the reported rate increase.

Figure 1

**Percentage Changes in Annual Suicide Rates (per 100,000, Age-Adjusted)**  
2014-2016 Compared Against 1999-2001

1 **Short Title:** Vital Signs: Identifying Increasing Trends in State Suicide Rates and Exploring Suicide’s Multiple  
2 Contributing Circumstances

3 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
4 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

5 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. Examining state-level trends in,  
6 and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention  
7 planning.

8 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
9 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
10 for 50 states and Washington, D.C. Data from the National Violent Death Reporting System (NVDRS), covering  
11 27 states in 2015, were used to examine contributing circumstances among decedents with and without known  
12 mental health problems (MHP).

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively.  
15 Among decedents in NVDRS, 54.0% did *not* have a known MHP. Among decedents with circumstance  
16 information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2%  
17 vs 49.7%) and recent/impending crises (32.9% vs 26.0%), were significantly more likely among those without a  
18 known MHP than decedents with MHP, but were common across groups.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. A variety of circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

24 **INTRODUCTION**

25 **BACKGROUND AND PURPOSE**

26 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
27 ≥10 years old (1). Between 1999 and 2015, suicide rates increased across both sexes, racial/ethnic groups, and  
28 urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
29 are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
30 for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the  
31 nation more than \$69 billion in direct medical and work loss costs (1).

32 The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
35 Despite the NSSP guidance, suicide prevention efforts largely focus on clinically-oriented interventions focused  
36 on people with mental health problems (MHP) or people who have attempted suicide (6). Other contributing  
37 circumstances include social isolation, relationship problems, economic problems, access to lethal means (e.g.,  
38 substances, firearms, bridges) among people at risk, and poor coping and problem-solving skills (5). Expanded  
39 awareness of these additional circumstances contributing to suicide risk and action to address them, can help  
40 reach the nation’s goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this

study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

85 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
86 These differences remained significant in the adjusted models.

87 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
88 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
89 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

90 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
91 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
92 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
93 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

94 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
95 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
96 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
97 were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
98 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
99 the preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the  
100 adjusted models. Among those with crises, intimate partner and physical health problems were the most  
101 common types for both groups and did not differ between them.

102 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
103 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
104 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
105 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
106 group were released from psychiatric facilities.

107 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
108 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than 1 in five people in  
109 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 110 **Conclusions and Comments**

111 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced rate increases of  
112 more than 30%. Rates increased significantly among males, (in 34 states) and females (in 43 states). This finding  
113 is consistent with prior research showing a decreasing gender gap in male-female suicide rates between 1999-  
114 2014 (3). Additional research into the specific causes of these trends is necessary. In the meantime, NVDRS  
115 provides insight into suicide circumstances and can help states identify prevention priorities.

116 Suicidologists regularly state that suicide 'is not caused by a single factor;' (5) however, suicide prevention  
117 research and practice is heavily weighted towards clinically-oriented activities (6). In contrast, the current study  
118 found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more  
119 from relationship issues and other life stressors such as criminal-legal, housing, and health problems. They also  
120 experienced more recent/impending crises which may point to suicides that took place with minimal  
121 deliberation (10). In addition to educating about how to respond to signs or disclosures of suicide risk, broader  
122 prevention to address non-clinical risks is critical and can include strengthening economic supports (e.g.,  
123 through housing stabilization policies, household financial support); teaching coping and problem-solving skills  
124 early in life to bolster healthy relationships over the life course; and promoting social connectedness to increase  
125 one's sense of belonging.

The above strategies are also applicable to people with MHP who, in the current study struggled more with job/financial problems, bereavement issues, and family crises, and who commonly experienced arguments/conflicts, intimate partner, and health problems. These findings support a body of literature indicating increased vulnerability among people with MHP to socio-economic and health problems (11). In the clinical realm, two-thirds of people with MHP had a history of any treatment and 54% were in treatment when they died. This suggests the need for broader implementation of evidence-based treatment (e.g., collaborative care, cognitive-behavioral therapy), greater access to behavioral health providers (especially in underserved areas), and expanded integration of physical and behavioral health within healthcare systems, especially through care transitions (12).

In addition to the abovementioned strategies, other components of a comprehensive approach include: creating protective environments by reducing access to lethal means (e.g., medications, firearms) among people at risk, creating workplace policies encouraging employee help-seeking and connectedness, and zoning to reduce alcohol-outlet density; better identifying people at risk; supporting friends/family after a suicide has taken place and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are underway planning such a comprehensive approach to suicide prevention (13).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population

(<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (14), however many methodological variations across studies exist (15). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem with many associated risk factors. States and communities can use NVDRS data to better understand their suicide problem and can use resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to implement evidence-based comprehensive suicide prevention to save lives.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System (NVDRS), covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. Among NVDRS decedents in 27 states, 54.0% did *not* have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across both sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on clinically-oriented interventions focused on mental health problems (MHP) and preventing re-attempts (6). Apart from MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this

study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
85 These differences remained significant in the adjusted models.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

89 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
90 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
91 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
92 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without known MHP versus those with known MHP had significantly greater likelihood of any  
94 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
95 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
96 were also more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
97 (10.7% vs. 6.2%), or eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the  
98 preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the  
99 adjusted models. Among those with crises, intimate partner problems were the most common types for both  
100 groups and did not differ between them. Similarly, physical health problems (23.2% and 21.4%) and job/financial  
101 problems (15.6% and 16.8%) did not differ between people without MHP and those with MPH, respectively, and  
102 were instead common to both groups.

103 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
104 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
105 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
106 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
107 group were released from psychiatric facilities.

108 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
109 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
110 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 111 **Conclusions and Comments**

112 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
113 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
114 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
115 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
116 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
117 circumstances and can help states identify prevention priorities.

118 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention  
119 research and practice is heavily weighted towards clinically-oriented activities focused on MHP (6). The current  
120 study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered  
121 more relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent  
122 or impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts  
123 occur with minimal deliberation (10).

124 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
125 half were in current treatment. This suggests that additional supports for this population are needed to keep  
126 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
127 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
128 behavioral health providers in underserved areas is needed, as is expansion of healthcare systems to integrate  
129 physical and behavioral health that better support suicide prevention and patient safety, especially through care  
130 transitions (11).

131 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
132 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
133 associated with mental health problems in the first place, and to support people with known MHP to decrease  
134 their risk of poor social, health, and economic outcomes (12).

135 Together, these results underscore the importance of comprehensive statewide suicide prevention activities  
136 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
137 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
138 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
139 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
140 emotional, and social support; and identifying and better supporting people at risk. Other strategies include  
141 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
142 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
143 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
144 reporting by the media in order to prevent suicide contagion (11). Some states, such as Colorado, are planning  
145 to implement such a comprehensive approach to suicide prevention (13).

146 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
147 UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing  
148 reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing  
149 estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included  
150 represent 49.6% of the population  
151 (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

152 Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the  
153 extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth  
154 interviews with next-of-kin often see greater attributions to mental disorders (14), however many  
155 methodological variations across studies exist (15). It is likely that some people without known MHP in the  
156 current study were experiencing mental health challenges that were unknown, and hence underreported by key  
157 informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad  
158 range of contributing circumstances.

159 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
160 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
161 *Technical Package of Policies, Programs, and Practices* (11) to better understand their suicide problem, prioritize  
162 evidence-based comprehensive suicide prevention, and save lives.

163

Stone\_Suicide Vital Signs MMWR 4.2.18 (Tables 2&3)

**Word Count:** 1879/1800

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.

Despite the NSSP guidance, suicide prevention efforts are largely clinically-oriented, focused on treating mental health problems (MHP) and preventing re-attempts (6). Apart from MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes

state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as [determining suicidal intent in younger children can be difficult](#) (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (665)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide [used](#) overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
85 These differences remained significant in the adjusted models.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

89 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
90 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
91 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
92 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without ~~known~~ MHP versus those with ~~known~~ MHP had significantly greater likelihood of any  
94 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
95 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
96 also were more likely to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems  
97 (10.7% vs. 6.2%), or eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the  
98 preceding or upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the  
99 adjusted models. Among all people with crises, intimate partner problems were the most common types and did  
100 not differ between-them by group. Similarly, among people without versus with MHP, physical health problems  
101 (23.2% and 21.4%) and job/financial problems (15.6% and 16.8%) were commonly experienced and did not  
102 differ by group.

103 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
104 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
105 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
106 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
107 group were released from psychiatric facilities.

108 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
109 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
110 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 111 Conclusions and Comments

112 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
113 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
114 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
115 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
116 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
117 circumstances and can help states identify prevention priorities.

118 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention  
119 research and practice is heavily oriented towards downstream treatment of MHP and prevention of reattempts.  
120 Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as  
121 the current study found that more than half of suicide decedents in NVDRS did not have a known MHP. This  
122 group suffered more from relationship problems and other life stressors such as criminal-legal matters,  
123 eviction/loss of home, and recent or impending crises.

Comment [zaf9]: I like the upstream and downstream focus. What do you think?

Similarly, people with MHP also experienced other life stressors such as job/financial, relationship, and/or physical health problems. These findings point to the need to both prevent the conditions associated with mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in current treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. y- Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrate physical and behavioral health that better support with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may Such strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

3 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

4 **Background:** Suicide rates in the United States have risen nearly 30% since 1999. There is no single cause of  
5 suicide. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends  
6 in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention  
7 planning.

8 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
9 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
10 for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states  
11 in 2015, were used to examine contributing circumstances among decedents with and without known mental  
12 health problems (MHP).

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In  
15 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with  
16 circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life  
17 stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among  
18 those without a known MHP than decedents with MHP, but were common across groups.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

24 **INTRODUCTION**

25 **BACKGROUND AND PURPOSE**

26 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
27 ≥10 years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and  
28 urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
29 are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
30 for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the  
31 nation more than \$69 billion in direct medical and work loss costs (1).

32 The *National Strategy for Suicide Prevention*(NSSP) (5) calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.

35 Despite the NSSP guidance, suicide prevention efforts are largely clinically-oriented, focused on treating mental  
36 health problems (MHP) and preventing re-attempts (6). Apart (including? from) MHP and prior attempts, other  
37 contributing circumstances to suicide include social and economic problems, access to lethal means (e.g.,  
38 substances, firearms, bridges) among people at risk, and poor coping and problem-solving skills (5). Expanded  
39 awareness of these additional circumstances contributing to suicide risk and action to address them, can help  
40 reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this

Comment [za19]: Maybe take out 'just'

Comment [za19]: From Jane: Suicide rates in the United States have risen nearly 30% since 1999. There is no single cause of suicidal behavior. Mental health problems (MHP) among suicide decedents are often identified through health care visits, and individuals seeking mental health services are at elevated risk for suicide. However, many other factors can contribute to suicide risk. Examining state-level trends and the multiple contributing circumstances to suicide can inform comprehensive state suicide prevention planning.

Comment [za19]: From Jane: Apart from MHP and prior attempts, other circumstances contributing to suicidal thoughts and behaviors include inadequate coping and problem-solving skills, inadequate support resources, social and economic problems, and access to lethal means (e.g., substances, firearms, bridges) (5). Expanded awareness of these additional circumstances contributing to suicide risk and taking action to address them, can help communities and states reach the nation's goal of reducing suicide deaths 20% by 2025 (7).

Comment [za19]: Richard suggests using this cleared language instead, "Despite the NSSP guidance, The NSSP IAAG was, however, unable to find any state or community implementing the full range of comprehensive, coordinated, and effective suicide prevention efforts across all relevant settings and populations."

He also says this isn't true. The field has

Comment [za19]: Instead of Apart from MHP and prior attempts, other contributing.. we could say in addition to or Including MHP

study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (665)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

85 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
86 These differences remained significant in the adjusted models.

87 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
88 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
89 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

90 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
91 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
92 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
93 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

94 Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship  
95 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
96 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely  
97 to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or  
98 eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or  
99 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
100 Among all people with crises, intimate partner problems were the most common types and did not differ by  
101 group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and  
102 job/financial problems (15.6% and 16.8%) were commonly experienced and did not differ by group.

103 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
104 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
105 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
106 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
107 group were released from psychiatric facilities.

108 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
109 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
110 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 111 Conclusions and Comments

112 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
113 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
114 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
115 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
116 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
117 circumstances and can help states identify prevention priorities.

118 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention  
119 research and practice is heavily oriented towards downstream treatment of MHP and prevention of reattempts.  
120 Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as  
121 the current study found that more than half of suicide decedents in NVDRS did not have a known MHP. This  
122 group suffered more from relationship problems and other life stressors such as criminal-legal matters,  
123 eviction/loss of home, and recent or impending crises.

124 Similarly, people with MHP also experienced other life stressors such as job/financial, relationship, and/or  
125 physical health problems. These findings point to the need to both prevent the conditions associated with

Comment [za19]: More likely to have experienced or anticipated a crisis

Comment [za19]: "much of suicide prevention practice has focused on identifying suicidal people in the community, so increased focus is needed on how to "move upstream" and prevent people from becoming suicidal people in the first place.

mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts are largely clinically-oriented, focused on treating mental health problems (MHP) and preventing re-attempts (6). Apart from MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes

state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (665)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
85 These differences remained significant in the adjusted models.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8) but more likely to test positive for alcohol (aOR=1.2, 95% CI=1.1-1.3).

89 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
90 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
91 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
92 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship  
94 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
95 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely  
96 to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or  
97 eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or  
98 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
99 Among all people with crises, intimate partner problems were the most common types and did not differ by  
100 group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and  
101 job/financial problems (15.6% and 16.8%) were commonly experienced and did not differ by group.

102 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
103 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
104 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
105 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 46.7% of this  
106 group were released from psychiatric facilities.

107 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
108 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
109 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 110 **Conclusions and Comments**

111 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
112 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
113 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
114 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
115 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
116 circumstances and can help states identify prevention priorities.

117 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention  
118 research and practice is heavily oriented towards downstream treatment of MHP and prevention of reattempts.  
119 Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as  
120 the current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This  
121 group suffered more from relationship problems and other life stressors such as criminal-legal matters,  
122 eviction/loss of home, and recent or impending crises.

123 Similarly, people with MHP also experienced other life stressors such as job/financial, relationship, and/or  
124 physical health problems. These findings point to the need to both prevent the conditions associated with

mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. However, any lack of awareness of decedent MHP suggests the importance of addressing the broad range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

**Short Title:** Vital Signs: Contributing Circumstances to Suicide and Increasing Trends in State Suicide Rates

Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan, MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor contributing to suicide. Examining state-level trends in, and the multiple contributing circumstances to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among people aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System for 50 states and Washington, D.C. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems (MHP).

**Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known MHP. Among people with circumstance information, several circumstances, including relationship problems/loss (45.1% vs 39.6%), life stressors (54.2% vs 49.7%), and recent/impending crises (32.9% vs 26.0%) were significantly more likely among those without a known MHP than decedents with MHP, but were common across groups.

**Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances contributed to suicides among people with and without known MHP.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help friends/family after a suicide occurs.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  $\geq 10$  years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of ~~e~~Emergency ~~d~~Department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention* (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such a ~~comprehensive~~ approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention ~~efforts are largely clinically-oriented, focused~~ on ~~identifying suicidal people, providing treating-treatment for~~ mental health problems (MHP) and preventing re-attempts (6). ~~Apart from~~In addition to MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms, ~~bridges~~) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates,

assesses the multiple contributing factors to suicide, and provides recommendations options for multi-level comprehensive suicide prevention based on the best available evidence.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (665)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% of those without known MHP and 15.3% of those with MPH people without and with MHP, respectively, ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

85 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
86 These differences remained significant in the adjusted models.

87 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
88 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
89 CI=0.7-0.8), such as opioids (aOR=.90 95% CI=0.81-.99) but more likely to test positive for alcohol (aOR=1.2, 95%  
90 CI=1.1-1.3).

91 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
92 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
93 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
94 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

95 Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship  
96 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
97 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely  
98 to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or  
99 eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or  
100 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
101 Among all people with crises, intimate partner problems were the most common types and did not differ by  
102 group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and  
103 job/financial problems (15.6% and 16.8%) were commonly experienced ~~and did not differ by~~ both groups.

104 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
105 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
106 released from a correctional facility (25.7% vs. 8.7%), ~~or~~ hospital (43.7% vs. 33.0%) ~~or other facility (e.g.,~~  
107 alcohol/substance treatment) (aOR=2.5 95% CI=1.8-3.3), than those with a known MHP. Among decedents with  
108 known MHP who were recently released from an institution (10.2%), 46.7% of this group were released from  
109 psychiatric facilities.

110 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
111 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
112 both groups disclosed suicide intent (22.4% vs. 24.5%).

### 113 Conclusions and Comments

114 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
115 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
116 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
117 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
118 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
119 circumstances and can help states identify prevention priorities.

120 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention  
121 ~~research and practice is heavily often~~ oriented towards downstream identification of suicidal people, treatment  
122 of MHP and prevention of reattempts. Additional focus on non-mental health factors, further upstream, is  
123 essential to a public health approach (10), as the current study found that more than half of suicide decedents in  
124 NVDRS did not have a known MHP. This group suffered more from relationship problems and other life stressors  
125 such as criminal-legal matters, eviction/loss of home, and recent or impending crises.

Comment [HDE()]: I would add in the %  
for opioids as it is timely and relevant

Similarly, people with MHP ~~also often~~ experienced relationship problems and other life stressors such as job/financial, ~~relationship,~~ and/or physical health problems. These findings point to the need to both help people manage prevent the conditions associated with mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known MHP suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

## INTRODUCTION

### BACKGROUND AND PURPOSE

In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people ≥10 years old (1). Between 1999 and 2015, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels (2, 3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are *increasing* (1, 4). Additionally, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased nearly 45% between 2001 and 2015 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention largely focuses on identifying suicidal people, providing treatment for mental health problems (MHP) and preventing re-attempts (6). In addition to MHP and prior attempts, other contributing circumstances to suicide include social and economic problems, access to lethal means (e.g., substances, firearms) among people at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them, can help reach the nation's goal of reducing suicide rates 20% by 2025 (7). To assist states in achieving this goal,

this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors to suicide, and provides options for multi-level comprehensive suicide prevention based on the best available evidence.

## METHODS

Suicide rates were analyzed for people aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics and circumstances of suicide decedents  $\geq 10$  years old, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance dependence, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (which had a consistently high rate throughout), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Table 1, Figure 1).

Modeled suicide rate trends indicated significant increases for 44 states, for males (34 states) and females (43 states), as well as for the U.S. overall (Table 1). Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%).

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407) in 27 states. While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; odds ratio (OR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (OR range: 1.2-2.0). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio aOR = 2.9, 95% CI = 2.2-3.8). Among adult decedents, 20.1% of those without known MHP and 15.3% of those with MPH ever served, or were currently serving, in the U.S. military.

While firearms were the most common method of suicide used overall (48.5%) and for both groups, decedents without known MHP were more likely to die by firearm (55.3% vs. 40.6%) and less likely to die by

84 hanging/strangulation/suffocation (26.9% vs 31.3%) or poisoning (10.4% vs 19.8%) than those with known MHP.  
85 These differences remained significant in the adjusted models.

86 Decedents without known MHP were less likely to receive toxicology testing. Among those with toxicology  
87 results, decedents without known MHP were less likely to test positive for any substance overall (aOR=0.8, 95%  
88 CI=0.7-0.8), such as opioids (aOR=.90 95% CI=0.81-.99) but more likely to test positive for alcohol (aOR=1.2, 95%  
89 CI=1.1-1.3).

90 All suicide decedents with MHP (N=9,407) and approximately 85% without known MHP (N=9,357) had available  
91 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
92 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
93 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

94 Decedents without, versus those with, known MHP, had significantly greater likelihood of any relationship  
95 problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%), arguments/conflicts  
96 (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They also were more likely  
97 to have experienced any life stressors (54.2% vs 49.7%), such as criminal-legal problems (10.7% vs. 6.2%), or  
98 eviction/loss of home (4.3% vs. 3.4%) and were more likely to have had a crisis within the preceding or  
99 upcoming two weeks (32.9% vs. 26.0%). All of these differences remained significant in the adjusted models.  
100 Among all people with crises, intimate partner problems were the most common types and did not differ by  
101 group. Similarly, among people without versus with MHP, physical health problems (23.2% and 21.4%) and  
102 job/financial problems (15.6% and 16.8%) were commonly experienced by both groups.

103 Decedents without known MHP had significantly lower odds of recent release from any institution (aOR=0.5,  
104 95% CI=0.4-0.5), but among those who were recently released (5.1%), they were significantly more likely to be  
105 released from a correctional facility (25.7% vs. 8.7%), hospital (43.7% vs. 33.0%), or other facility (e.g.,  
106 alcohol/substance treatment) (aOR=2.5 95% CI=1.8-3.3), than those with a known MHP. Among decedents with  
107 known MHP who were recently released from an institution (10.2%), 46.7% of this group were released from  
108 psychiatric facilities.

109 Decedents without known MHP, compared to those with MHP, were significantly less likely to have a history of  
110 suicidal ideation (23.0% vs. 40.8%) and prior suicide attempts (10.3% vs. 29.4%). More than one in five people in  
111 both groups disclosed suicide intent (22.4% vs. 24.5%).

## 112 **Conclusions and Comments**

113 From 1999-2016, 44 states saw significant increases in suicide rates and 25 states experienced substantial  
114 increases in suicide rates of more than 30%. Rates increased significantly among males, in 34 states, and  
115 females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-  
116 female suicide rates between 1999-2014 (3). Additional research into the specific causes of these trends is  
117 necessary. Fortunately, data from the 27 states participating in NVDRS provides important insight into suicide  
118 circumstances and can help states identify prevention priorities.

119 Suicidologists regularly state that suicide is not caused by a single factor; (5) however, suicide prevention is often  
120 oriented towards downstream identification of suicidal people, treatment of MHP and prevention of reattempts.  
121 Additional focus on non-mental health factors, further upstream, is essential to a public health approach (10), as  
122 the current study found that more than half of suicide decedents in NVDRS did *not* have a known MHP. This  
123 group suffered more from relationship problems and other life stressors such as criminal-legal matters,  
124 eviction/loss of home, and recent or impending crises.

Similarly, people with MHP often experienced relationship problems and other life stressors such as job/financial and/or physical health problems. These findings point to the need to both help people manage the conditions associated with mental health problems in the first place, and to support people with known MHP to decrease their risk of poor outcomes (11). Two-thirds of this group had a history of any mental health and/or substance abuse treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, greater access to behavioral health providers in underserved areas is needed, as is expansion of healthcare systems needed that integrates physical and behavioral health with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support; and identifying and better supporting people at risk (e.g., Veterans, people with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population

(<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>).

Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often see greater attributions to mental disorders (13), however many methodological variations across studies exist (14). It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known MHP suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

4 **Structured abstract (256/250 words—this word count is not included in the 1800 max for the remainder)**

5 **Background:** Overall suicide rates have been rising in the United States. Examining state-level trends in suicide  
6 and its multiple contributing circumstances, can inform comprehensive state suicide prevention planning.

7 **Methods:** Trends in age-adjusted suicide rates, by state and sex, among people aged  $\geq 10$  years, were assessed  
8 using data from the National Vital Statistics System. Changes in rates were examined across six consecutive  
9 three-year periods from 1999-2016. The National Violent Death Reporting System (2015), covering 27 states,  
10 was used to examine the precipitating circumstances among suicide decedents with and without known mental  
11 health problems (MHP).

12 **Results:** Forty-four states saw statistically significant suicide rate increases from 1999-2016. In 25 states, rates  
13 increased by 30% or more. Male suicide rates increased significantly in 34 states while female rates increased  
14 significantly in 43 states. People with (46%) and without (54%) known MHP had both differing and similar  
15 circumstances precipitating suicide. Several circumstance, such as any relationship problems/loss (39.6 and  
16 45.1%,  $p \leq .01$ ), any life stressors/loss (49.7 and 54.2%,  $p \leq .01$ ), and recent crises (26.0 and 32.9%,  $p \leq .01$ ),  
17 respectively, were more likely among those without known MHP, but were common across groups.

18 **Conclusions:** Suicide rates rose significantly across most states from 1999-2016. Varied circumstances beyond  
19 MHP alone contributed to suicides among people with and without known MHP.

20 **Implications for Public Health Practice:** States can use a comprehensive public health approach based on the  
21 best available evidence to prevent suicide risks before they occur, identify and support people already at risk,  
22 prevent-re-attempts, and help friends/family after a suicide occurs.

## 23 INTRODUCTION

### 24 BACKGROUND AND PURPOSE (259 words)

25 In 2016, nearly 45,000 suicides (15.6/100,000) occurred in the United States (U.S.), among people  $\geq 10$  years [1].  
26 Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels [2,  
27 3]. Suicide is the 10<sup>th</sup> leading cause of death and is among the only leading causes to be *increasing* [1, 4].  
28 Additionally, rates of Emergency Department visits for nonfatal self-harm injury, a key risk factor for suicide,  
29 increased more than 40% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation  
30 more than \$69 billion in direct medical and work loss costs [1].

31 The *National Strategy for Suicide Prevention (NSSP)* [5] calls for a public health approach to suicide with  
32 prevention efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal),  
33 of the social ecology. Such an approach underscores that suicide is rarely caused by any single factor alone, but  
34 rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on identifying  
35 and treating individuals with mental health problems (MHP) [6]. Other associated risk factors include social and  
36 economic problems, access to lethal means (e.g. substances, firearms, bridges) among people at risk, poor  
37 coping and problem-solving skills, and prior suicide attempts, among others [5]. Expanded awareness of the  
38 additional circumstances that contribute to suicide risk apart from MHP, can help reach the nation's goal of  
39 reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific

40 trends in suicide rates, assesses the multiple factors associated with suicide, and provides recommendations for  
41 multi-level comprehensive suicide prevention.

## 42 **METHODS (260 words)**

43 Suicide rate estimates and trend analyses were calculated for those aged 10 years and older (because of variability  
44 in attributions of suicidal intent, younger children are excluded) [8]. Age-specific suicide counts were tabulated  
45 based on National Vital Statistics System coded death certificate records (*International Classification of Diseases*  
46 *10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates  
47 were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data  
48 releases.

50 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
51 from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per  
52 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
53 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
54 are reported in terms of average annual percentage changes (AAPCs).

56 Data from 2015 from the 27 states with complete data participating in the National Violent Death Reporting  
57 System (NVDRS) were used to compare the characteristics among suicide decedents with and without known  
58 current mental health problems (MHP). MHP are defined in NVDRS as disorders and syndromes listed in the  
59 Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) [9], except alcohol and other  
60 substance use disorders (captured separately). NVDRS aggregates data from three primary data sources: death  
61 certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents  
62 with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate  
63 adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## 64 **RESULTS (595 words)**

65 The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia) to 29.2  
66 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates  
67 increased in all but one state (Nevada), with absolute increases ranging from +0.2 (Delaware) to +8.1 (Wyoming)  
68 per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with  
69 percentage increases of at least 30% observed in half of all states.

71 Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1).  
72 By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females.  
73 Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was  
74 +1.1% for males and +2.6% for females.

76 Suicide decedents with (N=9,407) and without (N=11,039) known MHP were compared. While both groups were  
77 predominately male and non-Hispanic white, suicide decedents without known MHP were more likely to be  
78 male (83.6% vs. 68.8%;  $p \leq .01$ ), and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-  
79 1.3] – [1.6-2.0]). They also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio  
80 [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results  
81 for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of those with known MHP and 20% without ever served  
82 in the U.S. military.

83 Although firearms were used most often in both groups, decedents with known MHP died by poisoning more  
84 than those without MHP (19.8% vs. 10.4%;  $p \leq .01$ ), most frequently by over-the-counter/otherwise unclassified  
85 drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

86 All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had precipitating  
87 circumstances information. People with MHP were more likely to have any substance abuse problems (31.6% vs.  
88 25%,  $p \leq .01$ ). While two-thirds of those with known MHP had a history of MH or substance abuse treatment  
89 (67.2%), just over half (54.0%) were in current mental health treatment at the time of their deaths.

90 Decedents without known MHP, versus those with MHP had a greater likelihood of any relationship  
91 problem/loss (45.1 and 39.6%,  $p \leq .01$ ), specifically intimate partner problems (30.2 and 24.1%,  $p \leq .01$ ),  
92 arguments/conflicts (17.5 and 13.6%,  $p \leq .01$ ), and recently perpetrating interpersonal violence (3.0 and 1.4%,  $p$   
93  $\leq .01$ ). They were also more likely to have experienced other life stressors, such as criminal legal problems (10.7  
94 and 6.2%,  $p \leq .01$ ) or eviction/loss of home (4.3 and 3.4%,  $p \leq .01$ ), and they were more likely to have had a crisis  
95 within the preceding or upcoming two weeks (32.9 and 26.0%,  $p < .01$ ). Among both groups, the most common  
96 crises were intimate partner (35.6%) and physical health (13.4%) problems.

97 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
98 those who were recently released, those without a known MHP were more likely to be released from a  
99 correctional facility (25.7% vs. 8.7%,  $p \leq .01$ ) or hospital (43.7% vs. 33.0%,  $p \leq .01$ ) than those with a known MHP.  
100 Among decedents with known MHP recently released from an institution (10.2%), 42.8% were released from  
101 psychiatric facilities.

102 Suicide decedents without known MHP were more likely to leave a suicide note (35.1 and 31.8%,  $p \leq .01$ ), while  
103 decedents with known MHP, compared to those without MHP, were more likely to have a history of suicidal  
104 ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  $p \leq .01$ ).

## 105 **Conclusions and Comments (715 words)**

106 From 1999-2016, 44 states saw significant suicide rate increases. Half of the states experienced increases of 30%  
107 or more. Rates increased significantly in 34 states among males and 43 states among females. More research  
108 into the causes of these trends is necessary [10].

109 One important factor associated with suicide is MHP. Nearly half of suicide decedents in NVDRS had a known  
110 MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicidal  
111 ideation (40.8%) and attempts (29.4%). While two-thirds of people with MHP had a history of MH and/or  
112 substance abuse treatment and over half were in treatment at the time of their deaths, additional support could  
113 help address the needs of this vulnerable population. This includes broader implementation of affordable and  
114 evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral therapy.  
115 Additionally, greater access to behavioral health providers, especially in underserved areas is important, as is  
116 healthcare systems change that supports suicide prevention and patient safety through care transitions [11].

117 While mental health problems are a significant contributor to suicide, 54% of suicide decedents in this study did  
118 *not* have a known MHP. This group suffered more relationship problems and life stressors such as criminal-legal  
119 matters, eviction/loss of home, and recent or impending crises. This is noteworthy in light of findings that  
120 suggest many suicides and attempts occur with minimal deliberation time, particularly among people without  
121 mental health disorders and who faced impending life crises [12]. People with known MHP also experienced  
122 other life stressors such as job and/or financial problems, relationship problems, and physical health problems.  
123 These findings point to the need to both prevent the conditions associated with mental health problems in the

124 first place and the need to support people with MHP to decrease their vulnerability to poor social, health, and  
125 economic outcomes [13].

126 These results underscore the importance of comprehensive state suicide prevention activities that go beyond a  
127 focus on MH treatment alone. Prevention strategies may include: strengthening economic supports (e.g.  
128 housing stabilization policies, household financial support), teaching coping and problem-solving skills, especially  
129 early in life to manage everyday stressors and prevent future relationship problems; and promoting social  
130 connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social  
131 support, as needed. Other strategies indicated by these results include creating protective environments (e.g.,  
132 reducing access to lethal means among people at risk, creating organizational and workplace policies to promote  
133 help-seeking and positive social norms), supporting family and friends after a suicide has taken place, and  
134 assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado,  
135 are planning and implementing a comprehensive approach to suicide prevention [14].

136 The study findings have at least three limitations. Related to state trend analyses, four states (MD, MA, RI, UT),  
137 rankings might have been impacted by large proportions of injury deaths of undetermined intent, or by  
138 decreased percentages of such deaths over time, which likely include some unrecognized suicides. Second,  
139 NVDRS is not yet nationally representative. This study used the most current data available which includes 27  
140 states that represent half (49.6%) of the U.S. population. Third, abstractors of NVDRS data are limited to data  
141 included in investigative reports. For example, medical and MH information are not captured directly from  
142 medical records but from key informants (e.g., family, friends) via coroner/medical examiner reports. Therefore,  
143 informant knowledge impacts the completeness and accuracy of the information reported, and studies including  
144 in-depth interviews with family members often see greater attributions to MH and substance abuse disorders,  
145 however methodological variation across studies exists [15]. It is likely that some people without known MHP in  
146 the current study were experiencing mental health challenges at the time of death that were either not known  
147 or reported by informants, or were not captured in NVDRS's primary data sources. The lack of awareness of a  
148 mental health problem suggests the importance of addressing the range of contributing circumstances.

149 Suicide is a growing public health problem. Mental illness is an important risk factor for suicide, and is one of  
150 many requiring preventive action. Data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical*  
151 *Package of Policies, Programs, and Practices* [11] can help states and communities better understand their  
152 suicide problem and prioritize comprehensive suicide prevention.

4 **Structured abstract** (256/252/250 words—this word count is not included in the 1800 max for the remainder)

5 **Background:** Overall suicide rates have been rising in the United States since 1999. Examining state-level trends  
6 in suicide and its multiple contributing circumstances, can inform comprehensive state suicide prevention  
7 planning.

8 **Methods:** Trends in age-adjusted suicide rates, by state and sex, among people aged ≥10 years, were assessed  
9 using data from the National Vital Statistics System. Changes in rates were examined across six consecutive  
10 three-year periods from 1999–2016. The CDC's National Violent Death Reporting System (2015), covering 27  
11 states, was used to examine the precipitating circumstances among suicide decedents with and without known  
12 mental health problems (MHP).

13 **Results:** Forty-four states saw statistically significant increases in suicide rates from 1999–  
14 2016 in 44 states. In 25 states, rates increased by 30% or more. Male suicide rates increased significantly in 34  
15 states, while female rates increased significantly in 43 states. People with (46%) and without (54%) known MHP  
16 had both differing and similar circumstances precipitating suicide. Several circumstances, such as any  
17 relationship problems/loss (39.6 and 45.1%,  $p \leq .01$ ), any life stressors/loss (49.7 and 54.2%,  $p \leq .01$ ), and recent  
18 crises (26.0 and 32.9%,  $p \leq .01$ ), respectively, were more likely among those without known MHP, but were  
19 common across groups.

20 **Conclusions:** Suicide rates rose significantly across most states from 1999–2016. Varied circumstances beyond  
21 MHP alone contributed to suicides among people with and without known MHP.

22 **Implications for Public Health Practice:** States can use a comprehensive public health approach based on the  
23 best available evidence to prevent suicide risks before they occur, identify and support people already at risk,  
24 prevent re-attempts, and help friends/family after a suicide occurs.

25 **INTRODUCTION**

26 **BACKGROUND AND PURPOSE** (255/260 words)

27 In 2016, nearly 45,000 suicides (15.6/100,000) occurred in the United States (U.S.), among people ≥10 years old  
28 [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels  
29 [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is among the only leading causes to be increasing [1, 4].  
30 Additionally, rates of Emergency Department visits for nonfatal self-harm injury, a key risk factor for suicide,  
31 increased more than 40% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation  
32 more than \$69 billion in direct medical and work loss costs [1].

33 The National Strategy for Suicide Prevention (NSSP) [5] calls for a public health approach to suicide with  
34 prevention with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and  
35 societal), of the social ecology. Such an approach underscores that suicide is rarely caused by any single factor  
36 alone, but rather, is multi-determined. Despite the NSSP guidance, suicide prevention efforts largely focus on  
37 identifying and treating individuals with mental health problems (MHP) [6]. Other associated contributing risk  
38 factors include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among  
39 people at risk, poor coping and problem-solving skills, and prior suicide attempts, among others [5]. Expanded

**Comment [BE():]** Sometimes it is referred to as a 'contributing circumstance' and sometimes its referred to as a 'contributing factor'. I wonder if its

**Comment [FC():]** Can a couple of words be added here to reflect a date since rates have been rising. I see word count is an issue and I think a couple of words can

**Comment [FC():]** Style consideration. Since focus on suicide and states is clear may not these words twice in sentence which would reduce word count. A few

**Comment [FC():]** The transition from reading NVDRS covers 27 states to methods to the first line in the results referring to 44 states made me pause and

**Comment [FC():]** Unclear if this was supposed to be a reference or can come out.

**Comment [JRV8]:** Just a suggestion and may not be feasible, but would suggest not using MHP through the document. Mental health problems doesn't seem

**Comment [BE():]** I think this is a significant finding should we say more about it the fact that it is increasing more in women?

**Comment [FC():]** I think edits are needed here for a few reasons. I am finding the statements that there are differences and similarities vague and hard to follow

**Comment [FC():]** Please double check. I am getting 15.9 from WISQARS

**Comment [BE():]** Can we be more specific – is it the only or is it one of only X leading causes increasing – 'among the only' is vague?

**Comment [FC():]** Please double check. Wonder if this might have been calculated for all ages and not limited to ≥10 years.

**Comment [JRV8]:** Suggest identifying this as a US Surgeon General report.

**Comment [BE():]** Is it better to say social ecology (which I think many think of social, environmental and economic) versus I think what is used most often the

awareness of the additional circumstances that contribute to suicide risk apart from MHP, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors associated with suicide, and provides recommendations for multi-level comprehensive suicide prevention.

#### METHODS (257/260 words)

Suicide rates were analyzed for those aged 10 years and older (because of variability in attributions of suicidal intent, younger children are excluded) [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision* [ICD-10] underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Data from 2015 from the 27 states with complete data participating in the CDC's National Violent Death Reporting System (NVDRS), ages 10 and older, were used to compare the characteristics among suicide decedents with and without known current mental health problems (MHP). MHP are defined in NVDRS as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) [9], except alcohol and other substance use disorders (captured separately). NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests; logistic regression was used to estimate adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

#### RESULTS (612/591 words)

The most recent overall suicide rates (representing 2014-2016) ranged from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year, a four-fold difference (Table 1). Across the entire study period, rates increased in all but one state (Nevada), with absolute increases ranging from +0.2 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with percentage increases of at least 30% observed in 25 states.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents with (N=9,407) and without (N=11,039) known MHP were compared. While both groups were predominately male and non-Hispanic white, suicide decedents without known MHP relative to those with known MHP were more likely to be male (83.6% vs. 68.8%;  $p \leq .01$ ), and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (adjusted odds ratio [aOR] = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of positive toxicology results for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Fifteen percent of these adult decedents with known MHP, and 20% without, ever had served or were serving in the U.S. military.

**Comment [BE():]** Is it really the 'nation's goal' – versus the goal set by the American Foundation for Suicide Prevention.

**Comment [JRV8]:** Sentence has a lot of different points. It may be easier to read if it were two sentences. Suggestion:

Data from the National Violent Death Reporting System (NVDRS) were used to compare characteristics among suicide decedents with and without known current mental health programs. Complete data from 27 states participating in NVDRS in 2015 were used for this analyses.

**Comment [FC():]** I am confused by how the alcohol and substance use disorder exception is described. DSM-5 does have an alcohol use disorder diagnosis and a substance use disorder dx.

**Comment [FC():]** Some labeling of the tables and how reflected in the text need some modification. There are current two "Table 1" in attachments (i.e., state trends; select demographics). The two NVDRS tables and figure 1 don't appear to

**Comment [BE():]** Per our discussion in our last VS group meeting, should we add a note that despite NV not increases, they still have a significantly high rate of suicide?

**Comment [FC():]** Please double check. Table reflects +0.8

**Comment [FC():]** Suggest revising in order to allow in the next sentence the comparison group to be clear and the order the %'s should be considered clearer. Tracked is an idea.

**Comment [FC():]** Wonder if need to be clear here this is limited to 18+. Tracked might be a simple approach to consider.

I have seen MMWR want to present %'s to first decimal place consistently. Here is

**Comment [JRV8]:** I realize this adds words so you may not be able to do this but the "ever" in the original sentence was confusing/stumbling block to me as I read. Not sure if the additional language is correct – past and active duty or just

86 Although firearms were used most often in both groups, decedents with known MHP died by poisoning more  
 87 than those without known MHP (19.8% vs. 10.4%;  $p \leq .01$ ), most frequently by over-the-counter/otherwise  
 88 unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).

89 All suicide decedents with known MHP (N=9,407) and approximately 85% without (N=9,357) had precipitating  
 90 circumstances information (Table 2 or 3??). People with known MHP were more likely to have any substance  
 91 abuse problems (31.6% vs. 25%,  $p \leq .01$ ). While two-thirds of those with known MHP had a history of MH or  
 92 substance abuse treatment (67.2%), just over half (54.0%) were in current treatment at the time of their deaths.

93 Decedents without known MHP, versus those with known MHP had a greater likelihood of any relationship  
 94 problem/loss (45.1% andvs. 39.6%,  $p \leq .01$ ), specifically intimate partner problems (30.2% andvs. 24.1%,  $p \leq .01$ ),  
 95 arguments/conflicts (17.5% andvs. 13.6%,  $p \leq .01$ ), and recently perpetrating interpersonal violence (3.0% andvs.  
 96 1.4%,  $p \leq .01$ ). They were also more likely to have experienced other life stressors, such as criminal-legal  
 97 problems (10.7% andvs. 6.2%,  $p \leq .01$ ) or eviction/loss of home (4.3% andvs. 3.4%,  $p \leq .01$ ), and they were more  
 98 likely to have had a crisis within the preceding or upcoming two weeks (32.9% andvs. 26.0%,  $p < .01$ ). Among  
 99 both groups, the most common crises were intimate partner (35.6%) and physical health (13.4%) problems.

100 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
 101 those who were recently released, those without a known MHP were more likely to be released from a  
 102 correctional facility (25.7% vs. 8.7%,  $p \leq .01$ ) or hospital (43.7% vs. 33.0%,  $p \leq .01$ ) than those with a known MHP.  
 103 Among decedents with known MHP recently released from an institution (10.2%), 42.8% were released from  
 104 psychiatric facilities.

105 Suicide decedents without known MHP were more likely than those without known MHP to leave a suicide note  
 106 (35.1% andvs. 31.8%,  $p \leq .01$ ), while dDecedents with known MHP, compared to those without known MHP,  
 107 were more likely to have a history of suicidal ideation (40.8% vs. 23.0%,  $p \leq .01$ ) and attempts (29.4% vs. 10.3%,  
 108  $p \leq .01$ ).

#### 109 **Conclusions and Comments (655/715 words)**

110 From 1999-2016, 44 states saw significant suicide rate increases. Half of the states experienced increases of 30%  
 111 or more. Rates increased significantly in 34 states among males and 43 states among females. More research  
 112 into the causes of these trends is necessary [10].

113 One important factor associated with suicide is MHP. Nearly half of suicide decedents in NVDRS had a known  
 114 MHP. This group was challenged by comorbid substance abuse problems (31.6%) and histories of suicidal  
 115 ideation (40.8%) and attempts (29.4%). While two-thirds of people with known MHP had a history of MH and/or  
 116 substance abuse treatment and over half were in treatment at the time of their deaths, additional support could  
 117 may help address the needs of this vulnerable population. This includes broader implementation of affordable  
 118 and evidence-based treatments, such as doctor-patient collaborative care models and cognitive-behavioral  
 119 therapy. Additionally, greater access to behavioral health providers, especially in underserved areas is  
 120 important, as is healthcare systems change that supports suicide prevention and patient safety through care  
 121 transitions [11].

122 While mental health problems are a significant contributor to suicide, 54% of suicide decedents in this study did  
 123 not have a known MHP. This group suffered more relationship problems and life stressors such as criminal-legal  
 124 matters, eviction/loss of home, and recent or impending crises. This is noteworthy in light of findings that  
 125 suggest many suicides and attempts occur with minimal deliberation time, particularly among people without  
 126 mental health disorders and who faced impending life crises [12].

**Comment [FC():** I think the comparison group %'s are needed. For instance, drugs (35.8% vs. 35.8%).

I think the presentation of the %'s would be easier here and later on in the results if the p's came out and the text could simply reflect "significant differences" or some variation of indicating in the groups were different.

**Comment [BE():** Sometimes criminal-legal is hyphenated and sometimes it's not.

**Comment [FC():** The % reported in this sentence appear to be only for the group with MHPs. Based on the sentence wording, the % for both groups need to be reported.

**Comment [FC():** Please double check number. Table reflects 33.8%

**Comment [FC():** My two cents: I think we should do more to raise attention to the fact that almost a quarter of both groups disclosed suicide intent. This is a true prevention opportunity so I think this is a common risk to highlight. Knowing space constraints, I think this is more important to highlight than the presence of a suicide note which often doesn't inform prevention. I suggest adding into results and into discussion.

**Comment [FC():** I feel that MMWRs typically don't do a lot of repeat of the specific data findings in the discussion. I think the numbers could come out here. I think it would be helpful to put this into a larger context, indicating whether this is consistent with other research. I also

**Comment [BE():** I would add the percentage in parenthesis (X%).

127

128 People with known MHP also experienced other life stressors such as job and/or financial ~~problems~~,  
 129 relationship ~~problems~~, and/or physical health problems. These findings point to the need to both prevent the  
 130 conditions associated with mental health problems in the first place and the need to support people with known  
 131 MHP to decrease their ~~vulnerability~~ to poor social, health, and economic outcomes [13].

132 These results underscore the importance of comprehensive statewide suicide prevention activities that go  
 133 beyond a focus on ~~MHmental health~~ treatment alone. Prevention strategies may include: strengthening  
 134 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
 135 problem-solving skills, especially early in life to manage everyday stressors and prevent future relationship  
 136 problems; and promoting social connectedness to increase a sense of belongingness and access to  
 137 informational, tangible, emotional, and social support, ~~as needed~~. Other strategies ~~indicated by these results~~  
 138 include creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
 139 organizational and workplace policies to promote help-seeking and positive social norms), supporting family and  
 140 friends after a suicide ~~has taken place~~, and assuring safe reporting by the media in order to prevent suicide  
 141 contagion [11]. Some states, such as Colorado, are planning and implementing a comprehensive statewide  
 142 approach to suicide prevention [14].

143 The ~~study~~ findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
 144 UT) might have been impacted by large proportions of injury deaths of undetermined intent, ~~or by decreased~~  
 145 ~~percentages of such deaths over time~~, which likely include some unrecognized suicides. Second, NVDRS is not  
 146 yet nationally representative, ~~and this study's~~. This study used the most current data available which data  
 147 includes 27 states that represent half (49.6%) of the U.S. population. Third, abstractors of NVDRS data are  
 148 limited to data included in investigative reports. ~~For example, mMedical and MHmental health information are~~  
 149 ~~not captured directly from medical records but come~~ from key informants (e.g., family, friends) via  
 150 coroner/medical examiner reports and can. Therefore, informant knowledge impacts the data completeness and  
 151 accuracy of the information reported, and Some studies including in-depth interviews with family members  
 152 show often see greater attributions to ~~MHmental health~~ and substance abuse disorders than medical records,  
 153 however methodological variation across studies exists [15]. It is likely that some people without known MHP in  
 154 the current study were experiencing mental health challenges at the time of death that were either not known  
 155 or ~~reported by informants~~ or were not captured in NVDRS's primary data sources. The lack of awareness of a  
 156 mental health problem suggests the importance of addressing the range of contributing circumstances.

157 Suicide is a growing public health problem. Mental illness is an important risk factor for suicide, and is one of  
 158 many requiring preventive action. Data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical*  
 159 *Package of Policies, Programs, and Practices* [11] can help states and communities better understand their  
 160 suicide problem and prioritize comprehensive suicide prevention.

166 **Author Affiliations:**

**Comment [FC():]** I suggest pulling this out into a separate paragraph. If contained in the above, it seems to undercut the main point that many suicides don't have MPH. A new paragraph might need a lead-in sentence or maybe start with the current last sentence to frame points about common risks.

**Comment [BE():]** Should this be 'and', 'or' or 'and/or'?

**Comment [JRV8]:** Suggest using "risk of" rather than "vulnerability to", as vulnerability sometimes can have negative connotations aligned with weakness.

**Comment [FC():]** I think it is fine that the TP strategies are presented in different areas of the discussion. I don't easily see "identify and support people at-risk". I think that can go in the proposed paragraph immediately above when talking about common risk factors. In adding that, suggest adding some examples of approaches (e.g., crisis intervention, gatekeeper training).

**Comment [FC():]** I am not easily following this point. Can this be stated more simply such as "...impacted by variations of undetermined injury deaths, which likely....

To help w/word count, offer a couple of suggestions in next few sentences to streamline. Certainly take/leave what you like and check for accuracy.

**Comment [BE():]** Do you mean 'NOT' reported by informants?

**Comment [FC():]** To me, this sentence puts the spotlight back on mental illness and makes it likely it will be the take home message of media reporting. If that isn't the goal of this VS, suggest framing broadly. Ideas: *Effective approaches are available to prevent or ameliorate many*

1 **Short title:** Vital Signs: Increasing Trends in State Suicide Rates and Contributing Circumstances among people  
2 ≥10 years

3 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
4 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

5 **Structured abstract (250/250 words—this word count is not included in the 1800 max for the remainder)**

6 **Background:** Suicide rates among people ~~aged~~ ≥10 years have risen nearly 30% since 1999. Mental health  
7 problems (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other  
8 contributing circumstances can inform comprehensive state suicide prevention planning.

9 **Methods:** Trends in age-adjusted suicide rates among people ~~aged~~ ≥10 years, by state and sex, across six  
10 consecutive three-year periods (1999-2016), were assessed using ~~data from~~ the National Vital Statistics System  
11 ~~infor~~ 50 states and Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27  
12 states in 2015, ~~examined (were used to examine)~~ precipitating circumstances among decedents ~~with and without~~  
13 ~~known MHP~~.

14 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
15 of ~~more than 30% or more~~. Rates increased significantly among males and females, in 34 and 43 states,  
16 respectively. Over half (54.0%) of people did *not* have a known MHP; 46.0% did. Groups experienced similar and  
17 differing circumstances and some circumstances were common to both. Among people ~~without known MHP,~~  
18 ~~compared to those with MHP~~, 45.1% and 39.6% ( $p<.01$ ) had any relationship problems/loss, 54.2% and 49.7%  
19 ( $p<.01$ ) had any life stressors/loss and 32.9% and 26.0% ( $p<.01$ ) had any recent/impending crises, respectively.

20 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
21 contributed to suicides among people ~~with and without known MHP~~.

22 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
23 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
24 friends/family after a suicide occurs.

## 25 INTRODUCTION

### 26 BACKGROUND AND PURPOSE (250/250 words)

27 In 2016, nearly 45,000 suicides (15.6/100,000 ~~age-adjusted~~) occurred in the United States (U.S.), among people  
28 ≥10 years old [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and  
29 urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes to be  
30 *increasing* [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for  
31 suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the  
32 nation more than \$69 billion in direct medical and work loss costs [1].

33 The *National Strategy for Suicide Prevention*(NSSP) [5] calls for a public health approach to suicide prevention  
34 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
35 an approach underscores that suicide is rarely caused by any single factor alone, but rather, is multi-determined.  
36 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
37 mental health problems (MHP) [6]. Other contributing factors include social and economic problems, access to  
38 lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills,  
39 and prior suicide attempts [5]. Expanded awareness of the additional circumstances that contribute to suicide

#### Comment [snk6]:

I've never seen the MMWR office strictly enforce the stated limit of 250 words for the Abstract. Here, I think we need to either say "aged ≥10 years" or "≥10 years old".

Another option would be to drop the phrase "among people aged ≥10 years" altogether right here, as this is a general lead-in statement, and just say "suicide rates", since the specific age range is documented in the Methods section just below.

#### Comment [snk6]:

Without this, it sounds like the National Vital Statistics System can be used like a query application.

#### Comment [snk6]:

Being fussy here, as I anticipate the MMWR editors will be as well.

#### Comment [snk6]:

The state ranked 25<sup>th</sup> (IN) had an increase of ~32%. The state ranked 26<sup>th</sup> (LA) had an increase of ~29%.

#### Comment [snk6]:

Consider adding.

risk apart from MHP, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS (255/250 words)

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods ~~from~~spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9]. For this study, alcohol and other substance use disorders were not defined as MHP, and were examined in both groups. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (584/600 words)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of at least more than 30% observed in 25 states.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served in the U.S. military.

**Comment [zaf9]:** Scott we had this as 0.2 before?? Can you confirm 0.8 is correct?

**Comment [snk6]:**

Thank you. It (+0.8) is correct. Just cross-checked against the actual SAS output and against Table 1 (where it is correct).

85 Although firearms were used most often, overall (48.5%), decedents with known MHP died by poisoning  
 86 significantly more than those without known MHP (19.8% vs. 10.4%), most frequently by over-the-  
 87 counter/otherwise unclassified drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines  
 88 (25.1%).

89 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
 90 circumstances information (Table 3). People without known MHP were 30% less likely to have any substance  
 91 abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental  
 92 health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without known MHP, versus those with known MHP had a significantly greater likelihood of any  
 94 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
 95 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
 96 were also significantly more likely to have experienced other life stressors, such as criminal-legal problems  
 97 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
 98 the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common crises were  
 99 intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

100 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
 101 those who were recently released, those without a known MHP were significantly more likely to be released  
 102 from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known MHP. Among  
 103 decedents with known MHP recently released from an institution (10.2%), 42.8% were released from psychiatric  
 104 facilities.

105 Decedents without known MHP, compared to those with known MHP, were 60% less likely to have a history of  
 106 suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and 70% less likely to have an attempt history (aOR=0.3, 95% CI=0.3-  
 107 0.3). Both groups disclosed suicide intent frequently, (22.4% vs. 24.5%), respectively.

#### 108 **Conclusions and Comments (680/700 words)**

109 The rise in suicide rates in the overall U.S. has been observed for many years [10]. Reporting of state-specific  
 110 trends ~~overall and by sex is much~~ less common. Similarly, while geographic patterning in suicide rates have  
 111 frequently been reported [10], the current findings point to a disturbing pattern of increases nationwide.  
 112 Understanding the contributing circumstances of suicide is obligatory for prevention practice and decision-  
 113 making.

114 Research and prevention practitioners regularly state that suicide is not caused by a single factor, however, the  
 115 focus of suicide research and prevention practices almost solely focus on MHP. The current study found that  
 116 more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship  
 117 problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.  
 118 This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
 119 deliberation [12].

120 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
 121 half were in current treatment. This suggests that additional supports for this population are needed to keep  
 122 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
 123 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
 124 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems

#### **Comment [snk6]:**

Maybe we can drop this phrase without taking away from the intended message, and save a few words?

#### **Comment [snk6]:**

Much less common or somewhat less common?

needed that integrate physical and behavioral health and that better support suicide prevention and patient safety, especially through care transitions [11].

Study findings indicate that people with known MHP also experienced other life stressors such as job/financial, relationship, and/or physical health problems. These findings point to the need to both prevent the conditions associated with mental health problems in the first place and the need to support people with known MHP to decrease their risk of poor social, health, and economic outcomes [13].

These results, together, underscore the importance of comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, and identifying and better supporting people at risk. Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning and implementing such a comprehensive approach to suicide prevention [14].

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing suicide-ratespotentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (i.e. increasing suicide-ratespotentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative, the 27 states included in the current study represent 49.6% of the U.S. population. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including in-depth interviews with next-of-kin often see greater attributions to MHP and substance abuse disorders, however many methodological variations across studies exist [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of addressing the range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and prioritize evidence-based comprehensive suicide prevention.

**Comment [snk6]:**

More precise explanation of the *potential* influences, at the expense of just a few added words.

6 **Background:** Suicide rates among people ≥10 years have risen nearly 30% since 1999. Mental health problems  
7 (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing  
8 circumstances can inform comprehensive state suicide prevention planning.

9 **Methods:** Trends in age-adjusted suicide rates among people ≥10 years, by state and sex, across six consecutive  
10 three-year periods (1999–2016), were assessed using the National Vital Statistics System in 50 states and  
11 Washington, D.C. (D.C.). Data from the National Violent Death Reporting System, covering 27 states in 2015, was  
12 used to examine contributing precipitating circumstances among decedents with and without known MHP.

13 **Results:** From 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
15 half (54.0%) of decedents people did not have a known MHP; 46.0% did. Among decedents with circumstance  
16 information, those without known MHP were more likely (all  $p < .01$ ) than those with a MHP to have relationship  
17 problems/loss (Groups experienced similar and differing circumstances and some circumstances were common  
18 to both. Among people without known MHP, compared to those with MHP), 45.1% vs and 39.6%), life  
19 stressors/loss ( $p < .01$ ) had any relationship problems/loss, 54.2% vs and 49.7% ( $p < .01$ ) and  
20 recent/impending crises (32.9% vs 26.0%), but these circumstances were common across groups. ad any life  
21 stressors/loss and 32.9% and 26.0% ( $p < .01$ ) had any recent/impending crises, respectively.

22 **Conclusions:** Suicide rates increased significantly across most states from 1999–2016. Various circumstances  
23 contributed to suicides among people with and without known MHP.

24 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
25 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
26 friends/family after a suicide occurs.

## 27 INTRODUCTION

### 28 BACKGROUND AND PURPOSE (250/250 words)

29 In 2016, nearly 45,000 suicides (15.6/100,000) occurred in the United States (U.S.), among people ≥10 years old  
30 [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels  
31 [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are to be increasing  
32 [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide,  
33 increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation more  
34 than \$69 billion in direct medical and work loss costs [1].

35 The *National Strategy for Suicide Prevention* (NSSP) [5] calls for a public health approach to suicide prevention  
36 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
37 an approach underscores that suicide is rarely caused by any single factor alone, but rather, is multi-determined.  
38 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
39 mental health problems (MHP) [6]. Other contributing factors/circumstances include social and economic

**Comment [BE()]:** Sometimes it is referred to as a 'contributing circumstance' and sometimes its referred to as a 'contributing factor'. I wonder if its best to be consistent so as not to confuse the reader that the two are different. From a plain language perspective, I prefer contributing factors ☺. Also, sometimes it is referred to a just 'contributing factor' while other times it is referred to as 'contributing risk factor'. Also, sometime it is referred to as 'contributing' and sometimes as 'associated'. Should we be consistent?

**I FOUND:**  
CONTRIBUTING CIRCUMSTANCES=3  
PRECIPITATING CIRCUMSTANCES=1  
CIRCUMSTANCES (ALONE)=6  
CONTRIBUTING FACTORS=3  
FACTORS (ALONE)=3  
RISK FACTORS=2

**Comment [tgs9]:** I think we can say contributing circumstances a few times in the text and then just use circumstances.

**Comment [za19]:** Is this still accurate?

**Comment [tgs9]:** Some editing is needed because this read like the data examined circumstances.

**Comment [za19]:** Switched the order here

**Comment [tgs9]:** I saw that Cory made a good suggestion to say among those with circumstance information. If we make one point about the p-value we can save words. The edits I suggested allow us that there are differences but these are common for both.

problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## **METHODS (255/250 words)**

Suicide rates were analyzed for people  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [9]. For this study, alcohol and other substance use disorders were not defined as MHP, and were examined in both groups. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## **RESULTS (584/600 words)**

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of at least 30% observed in 25 states.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2,

**Comment [zaf9]:** The comment made was that it wasn't clear how we defined MHP since substance use disorders are a diagnosis in DSM-V. Changed this to be more straightforward.

**Comment [za19]:** Scott we had this as 0.2 before?? Can you confirm 0.8 is correct?

86 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever  
 87 served in the U.S. ~~military~~.

88 Although firearms were used most often, overall (48.5%), decedents with known MHP ~~were more likely to die~~  
 89 ~~by suffocation (31.3 vs. 26.9%) and poisoning (19.8% vs. 10.4%) significantly more than those without known~~  
 90 ~~MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise-unclassified (drugs (35.8%), opioids~~  
 91 ~~(32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).~~

92 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
 93 circumstances information (Table 3). People without known MHP were ~~30%~~ less likely to have any substance  
 94 abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental  
 95 health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

96 ~~Decedents without known MHP, versus those with known MHP had a significantly greater likelihood of any~~  
 97 ~~relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),~~  
 98 ~~arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They~~  
 99 ~~were also significantly more likely to have experienced other life stressors, such as criminal-legal problems~~  
 100 ~~(10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within~~  
 101 ~~the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common crises were~~  
 102 ~~intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.~~

103 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
 104 those who were recently released (~~5.1%~~), those without a known MHP were significantly more likely to be  
 105 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
 106 MHP. Among decedents with known MHP recently released from an institution (10.2%), 42.8% were released  
 107 from psychiatric facilities.

108 ~~Decedents without known MHP, compared to those with known MHP, were 60% less likely to have a history of~~  
 109 ~~suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and 70% less likely to have an prior suicide attempt history~~  
 110 ~~(aOR=0.3, 95% CI=0.3-0.3). Both groups disclosed suicide intent frequently, (22.4% vs. 24.5%), respectively.~~

# 111 Conclusions and Comments (680/700 words)

112 The rise in suicide rates in the overall U.S. has been observed for many years [10]. ~~Reporting of state-specific~~  
 113 ~~trends overall and by sex is much less common.~~ Similarly, while geographic patterning in suicide rates have  
 114 frequently been reported [10], the current findings point to a disturbing pattern of increases nationwide.  
 115 Understanding the contributing circumstances of suicide is obligatory for prevention practice and decision-  
 116 making.

117 Researchers and ~~prevention~~-practitioners regularly state that suicide is not caused by a single factor, however,  
 118 the focus of suicide research and prevention practices almost solely focus on MHP. The current study found that  
 119 more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship  
 120 problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.  
 121 This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
 122 deliberation [12].

123 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
 124 half were in current treatment. This suggests that additional supports for this population are needed to keep  
 125 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
 126 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to

Comment [za9]: Malia wanted to know if we could say "had served or were serving" in the U.S. Military.

Comment [tgs9]: I think that is fine.

Comment [FC]: I think the comparison group %'s are needed. For instance, drugs (35.8% vs. 35.8%).

I think the presentation of the %'s would be easier here and later on in the results if the p's came out and the text could simply reflect "significant differences" or some variation of indicating in the groups were different.

I DIDN'T CHANGE THIS B/C IT OPENS UP THE ISSUE OF PEOPLE W/O MHP TAKING ANTIDEP ETC

Do we even need to give this distribution? We don't talk about the types in the discussion

Comment [za9]: I kept this paragraph confined to percentages but did add some additional aOR's in other places.

Comment [tgs9]: We should be consistent and add this if we have the 10.2% below.

Comment [za9]: We were asked to include disclosure of suicide intent. Also, changed the formatting here a bit.

Comment [tgs9]: Why did you add this? It sounds like others have done it already. I think the last version of the start of the conclusion was more compelling.

behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems needed that integrate physical and behavioral health and that better support suicide prevention and patient safety, especially through care transitions [11].

Study findings indicate that people with known MHP also experienced other life stressors such as job/financial, relationship, and/or physical health problems. These findings point to the need to both prevent the conditions associated with mental health problems in the first place and the need to support people with known MHP to decrease their risk of poor social, health, and economic outcomes [13].

These results, together, underscore the importance of comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, and identifying and better supporting people at risk. Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning and implementing such a comprehensive approach to suicide prevention [14].

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS is not yet nationally representative, the 27 states included in the current study represent 49.6% of the U.S. population. Third, abstractors of NVDRS data are limited to information contained in investigative reports.

Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including in-depth interviews with next-of-kin often see greater attributions to MHP and substance abuse disorders, however many methodological variations across studies exist [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of addressing the range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and prioritize evidence-based comprehensive suicide prevention.

1 **Short title:** Vital Signs: Increasing Trends in State Suicide Rates and Contributing Circumstances among people  
2 ≥10 years

3 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
4 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

5 **Structured abstract (250/250 words—this word count is not included in the 1800 max for the remainder)**

6 **Background:** Suicide rates among people ≥10 years have risen nearly 30% since 1999. Mental health problems  
7 (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing  
8 circumstances can inform comprehensive state suicide prevention planning.

9 **Methods:** Trends in age-adjusted suicide rates among people ≥10 years, by state and sex, across six consecutive  
10 three-year periods (1999-2016), were assessed using the National Vital Statistics System in 50 states and  
11 Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27 states in 2015, was  
12 used to examine contributing circumstances among decedents with and without known MHP.

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
15 half (54.0%) of decedents did not have a known MHP. Among decedents with circumstance information, those  
16 without known MHP were more likely (all  $p \leq .01$ ) than those with a MHP to have relationship problems/loss  
17 (45.1% vs 39.6%), life stressors/loss (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), but these  
18 circumstances were common across groups.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

## 24 INTRODUCTION

### 25 BACKGROUND AND PURPOSE (250/250 words)

26 In 2016, nearly 45,000 suicides (15.6/100,000) occurred in the United States (U.S.), among people ≥10 years old  
27 [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels  
28 [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are increasing [1, 4].  
29 Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased  
30 nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation more than \$69  
31 billion in direct medical and work loss costs [1].

32 The *National Strategy for Suicide Prevention (NSSP)* [5] calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
35 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
36 mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems,  
37 access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-  
38 solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that  
39 contribute to suicide risk apart from MHP, can help reach the nation's goal of reducing suicide rates 20% by

**Comment [BE():]** Sometimes it is referred to as a 'contributing circumstance' and sometimes its referred to as a 'contributing factor'. I wonder if its best to be consistent so as not to confuse the reader that the two are different. From a plain language perspective, I prefer contributing factors ☺. Also, sometimes it is referred to a just 'contributing factor' while other times it is referred to as 'contributing risk factor'. Also, sometime it is referred to as 'contributing' and sometimes as 'associated'. Should we be consistent?

**I FOUND:**  
CONTRIBUTING CIRCUMSTANCES=3  
PRECIPITATING CIRCUMSTANCES=1  
CIRCUMSTANCES (ALONE)=6  
CONTRIBUTING FACTORS=3  
FACTORS (ALONE)=3  
RISK FACTORS=2

**Comment [tgs9]:** I think we can say contributing circumstances a few times in the text and then just use circumstances.

**Comment [za19]:** Is this still accurate?

**Comment [tgs9]:** Some editing is needed because this read like the data examined circumstances.

**Comment [za19]:** Switched the order here

**Comment [tgs9]:** I saw that Cory made a good suggestion to say among those with circumstance information. If we make one point about the p-value we can save words. The edits I suggested allow us that there are differences but these are common for both.

2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## METHODS (255/250 words)

Suicide rates were analyzed for people  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9]. For this study, alcohol and other substance use disorders were not defined as MHP, and were examined in both groups. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## RESULTS (584/600 words)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of at least 30% observed in 25 states.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served in the U.S. military.

**Comment [zaf9]:** The comment made was that it wasn't clear how we defined MHP since substance use disorders are a diagnosis in DSM-V. Changed this to be more straightforward.

**Comment [zaf9]:** Scott we had this as 0.2 before?? Can you confirm 0.8 is correct?

**Comment [zaf9]:** Malia wanted to know if we could say "had served or were serving" in the U.S. Military.

**Comment [tgs9]:** I think that is fine.

85 Although firearms were used most often, overall (48.5%), decedents with known MHP were more likely to die by  
86 suffocation (31.3 vs. 26.9%) and poisoning (19.8% vs. 10.4%) than those without known MHP.

87 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
88 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
89 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
90 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

91 Decedents without known MHP, versus those with known MHP had a significantly greater likelihood of any  
92 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
93 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
94 were also significantly more likely to have experienced other life stressors, such as criminal-legal problems  
95 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
96 the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common crises were  
97 intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

98 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
99 those who were recently released (5.1%), those without a known MHP were significantly more likely to be  
100 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
101 MHP. Among decedents with known MHP recently released from an institution (10.2%), 42.8% were released  
102 from psychiatric facilities.

103 Decedents without known MHP, compared to those with MHP, were less likely to have a history of suicidal  
104 ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). Both groups disclosed  
105 suicide intent frequently, (22.4% vs. 24.5%), respectively.

#### 106 Conclusions and Comments (680/700 words)

107 The rise in suicide rates in the overall U.S. has been observed for many years [10]. Reporting of state-specific  
108 trends overall and by sex is much less common. Similarly, while geographic patterning in suicide rates have  
109 frequently been reported [10], the current findings point to a disturbing pattern of increases nationwide.  
110 Understanding the contributing circumstances of suicide is obligatory for prevention practice and decision-  
111 making.

112 Researchers and practitioners regularly state that suicide is not caused by a single factor, however, the focus of  
113 suicide research and prevention practices almost solely focus on MHP. The current study found that more than  
114 half of suicide decedents in NVDRS did not have a known MHP. This group suffered more relationship problems  
115 and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises. This is  
116 particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
117 deliberation [12].

118 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
119 half were in current treatment. This suggests that additional supports for this population are needed to keep  
120 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
121 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
122 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems  
123 needed that integrate physical and behavioral health and that better support suicide prevention and patient  
124 safety, especially through care transitions [11].

**Comment [FC]:** I think the comparison group %'s are needed. For instance, drugs (35.8% vs. 35.8%).

I think the presentation of the %'s would be easier here and later on in the results if the p's came out and the text could simply reflect "significant differences" or some variation of indicating in the groups were different.

**I DIDN'T CHANGE THIS B/C IT OPENS UP THE ISSUE OF PEOPLE W/O MHP TAKING ANTIDEP ETC**

Do we even need to give this distribution? We don't talk about the types in the discussion

**Comment [za19]:** I kept this paragraph confined to percentages but did add some additional aOR's in other places.

**Comment [tgs9]:** We should be consistent and add this if we have the 10.2% below.

**Comment [za19]:** We were asked to include disclosure of suicide intent. Also, changed the formatting here a bit.

**Comment [tgs9]:** Why did you add this? It sounds like others have done it already. I think the last version of the start of the conclusion was more compelling.

Study findings indicate that people with known MHP also experienced other life stressors such as job/financial, relationship, and/or physical health problems. These findings point to the need to both prevent the conditions associated with mental health problems in the first place and the need to support people with known MHP to decrease their risk of poor social, health, and economic outcomes [13].

These results, together, underscore the importance of comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, and identifying and better supporting people at risk. Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning and implementing such a comprehensive approach to suicide prevention [14].

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS is not yet nationally representative, the 27 states included in the current study represent 49.6% of the U.S. population. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including in-depth interviews with next-of-kin often see greater attributions to MHP (and substance abuse disorders), however many methodological variations across studies exist [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of addressing the range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and prioritize evidence-based comprehensive suicide prevention.

1 **Short title:** Vital Signs: Increasing Trends in State Suicide Rates and Contributing Circumstances of Suicide among  
2 people ≥10 years

3 Deborah M. Stone, ScD;<sup>1</sup> Thomas R. Simon PhD;<sup>1</sup> Katherine A. Fowler, PhD;<sup>1</sup> Scott R. Kegler, PhD;<sup>2</sup> Keming Yuan,  
4 MS;<sup>1</sup> Kristin M. Holland, PhD;<sup>1</sup> Asha Z. Ivey-Stephenson, PhD;<sup>1</sup> Alex E. Crosby, MD<sup>1</sup>

5 **Structured abstract (250/250 words—this word count is not included in the 1800 max for the remainder)**

6 **Background:** Suicide rates among people ≥10 years have risen nearly 30% since 1999. Mental health problems  
7 (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing  
8 circumstances can inform comprehensive state suicide prevention planning.

9 **Methods:** Trends in age-adjusted suicide rates among people ≥10 years, by state and sex, across six consecutive  
10 three-year periods (1999-2016), were assessed using the National Vital Statistics System in 50 states and  
11 Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27 states in 2015,  
12 examined precipitating circumstances among decedents with and without known MHP.

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
15 half (54.0%) of people did not have a known MHP; 46.0% did. Groups experienced similar and differing  
16 circumstances and some circumstances were common to both. Among people without known MHP, compared  
17 to those with MHP, 45.1% and 39.6% ( $p<.01$ ) had any relationship problems/loss, 54.2% and 49.7% ( $p\leq.01$ ) had  
18 any life stressors/loss and 32.9% and 26.0% ( $p\leq.01$ ) had any recent/impending crises, respectively.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

## 24 INTRODUCTION

### 25 BACKGROUND AND PURPOSE (250/250 words)

26 In 2016, nearly 45,000 suicides (15.6/100,000) occurred in the United States (U.S.), among people aged ≥10  
27 years old [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and  
28 urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes to be  
29 increasing [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for  
30 suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the  
31 nation more than \$69 billion in direct medical and work loss costs [1].

32 The *National Strategy for Suicide Prevention* (NSSP) [5] calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor alone, but rather, is multi-determined.  
35 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
36 mental health problems (MHP) [6]. Other contributing factors include social and economic problems, access to  
37 lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills,  
38 and prior suicide attempts [5]. Expanded awareness of the additional circumstances that contribute to suicide  
39 risk apart from MHP, and preventive action can help reach the nation's goal of reducing suicide rates 20% by

**Comment [BE()]:** Sometimes it is referred to as a 'contributing circumstance' and sometimes its referred to as a 'contributing factor'. I wonder if its best to be consistent so as not to confuse the reader that the two are different. From a plain language perspective, I prefer contributing factors ☺. Also, sometimes it is referred to a just 'contributing factor' while other times it is referred to as 'contributing risk factor'. Also, sometime it is referred to as 'contributing' and sometimes as 'associated'. Should we be consistent?

**I FOUND:**  
CONTRIBUTING CIRCUMSTANCES=3  
PRECIPITATING CIRCUMSTANCES=1  
CIRCUMSTANCES (ALONE)=6  
CONTRIBUTING FACTORS=3  
FACTORS (ALONE)=3  
RISK FACTORS=2

**Comment [za19]:** Is this still accurate?

**Comment [za19]:** Switched the order here

40 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses  
 41 the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide  
 42 prevention.

#### 43 **METHODS (255/250 words)**

44 Suicide rates were analyzed for people  $\geq 10$  years only, as attributions of suicidal intent in younger children are  
 45 variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
 46 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
 47 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
 48 Health Statistics bridged-race population data releases.

49 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
 50 from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per  
 51 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
 52 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
 53 are reported in terms of average annual percentage changes (AAPCs).

54 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known  
 55 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
 56 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders listed in the Diagnostic and Statistical  
 57 Manual of Mental Disorders, Fifth Edition [9]. For this study, alcohol and other substance use disorders were not  
 58 defined as MHP, and were examined in both groups. NVDRS aggregates data from three primary data sources:  
 59 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
 60 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
 61 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
 62 race/ethnicity.

#### 63 **RESULTS (584/600 words)**

64 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
 65 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
 66 Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1  
 67 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota),  
 68 with increases of at least 30% observed in 25 states.

69 Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1).  
 70 By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females.  
 71 Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was  
 72 +1.1% for males and +2.6% for females.

73 Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407). While all  
 74 decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known  
 75 MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI  
 76 = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide  
 77 decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9,  
 78 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2,  
 79 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever  
 80 served in the U.S. military.

**Comment [za19]:** The comment made was that it wasn't clear how we defined MHP since substance use disorders are a diagnosis in DSM-V. Changed this to be more straightforward.

**Comment [za19]:** Scott we had this as 0.2 before?? Can you confirm 0.8 is correct?

**Comment [za19]:** Malia wanted to know if we could say "had served or were serving" in the U.S. Military.

85 Although firearms were used most often, overall (48.5%), decedents with known MHP died by poisoning  
 86 significantly more than those without known MHP (19.8% vs. 10.4%), most frequently by over-the-  
 87 counter/otherwise unclassified (drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines  
 88 (25.1%).

89 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
 90 circumstances information (Table 3). People without known MHP were 30% less likely to have any substance  
 91 abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental  
 92 health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

93 Decedents without known MHP, versus those with known MHP had a significantly greater likelihood of any  
 94 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
 95 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
 96 were also significantly more likely to have experienced other life stressors, such as criminal-legal problems  
 97 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
 98 the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common crises were  
 99 intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

100 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
 101 those who were recently released, those without a known MHP were significantly more likely to be released  
 102 from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known MHP. Among  
 103 decedents with known MHP recently released from an institution (10.2%), 42.8% were released from psychiatric  
 104 facilities.

105 Decedents without known MHP, compared to those with known MHP, were 60% less likely to have a history of  
 106 suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and 70% less likely to have an attempt history (aOR=0.3, 95% CI=0.3-  
 107 0.3). Both groups disclosed suicide intent frequently, (22.4% vs. 24.5%), respectively.

#### 108 Conclusions and Comments (680/700 words)

109 The rise in suicide rates in the overall U.S. has been observed for many years [10]. Reporting of state-specific  
 110 trends overall and by sex is much less common. Similarly, while geographic patterning in suicide rates have  
 111 frequently been reported [10], the current findings point to a disturbing pattern of increases nationwide.  
 112 Understanding the contributing circumstances of suicide is obligatory for prevention practice and decision-  
 113 making.

114 Research and prevention practitioners regularly state that suicide is not caused by a single factor, however, the  
 115 focus of suicide research and prevention practices almost solely focus on MHP. The current study found that  
 116 more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship  
 117 problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.  
 118 This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
 119 deliberation [12].

120 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
 121 half were in current treatment. This suggests that additional supports for this population are needed to keep  
 122 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
 123 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
 124 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems

**Comment [FC]:** I think the comparison group %'s are needed. For instance, drugs (35.8% vs. 35.8%).

I think the presentation of the %'s would be easier here and later on in the results if the p's came out and the text could simply reflect "significant differences" or some variation of indicating in the groups were different.

I DIDN'T CHANGE THIS B/C IT OPENS UP THE ISSUE OF PEOPLE W/O MHP TAKING ANTIDEP ETC

**Comment [zaf9]:** I kept this paragraph confined to percentages but did add some additional aOR's in other places.

**Comment [zaf9]:** We were asked to include disclosure of suicide intent. Also, changed the formatting here a bit.

**Comment [zaf9]:** wisqars

**Comment [zaf9]:** national strategy

needed that integrate physical and behavioral health and that better support suicide prevention and patient safety, especially through care transitions [11].

Study findings indicate that people with known MHP also experienced other life stressors such as job/financial, relationship, and/or physical health problems. These findings point to the need to both prevent the conditions associated with mental health problems in the first place and the need to support people with known MHP to decrease their risk of poor social, health, and economic outcomes [13].

These results, together, underscore the importance of comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, and identifying and better supporting people at risk. Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning and implementing such a comprehensive approach to suicide prevention [14].

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS is not yet nationally representative, the 27 states included in the current study represent 49.6% of the U.S. population. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including in-depth interviews with next-of-kin often see greater attributions to MHP and substance abuse disorders, however many methodological variations across studies exist [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of addressing the range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and prioritize evidence-based comprehensive suicide prevention.

5 **Structured abstract (250/250 words—this word count is not included in the 1800 max for the remainder)**

6 **Background:** Suicide rates among people ≥10 years have risen nearly 30% since 1999. Mental health problems  
7 (MHP) are just one factor contributing to suicide. Examining state-level trends in suicide and other contributing  
8 circumstances can inform comprehensive state suicide prevention planning.

9 **Methods:** Trends in age-adjusted suicide rates among people ≥10 years, by state and sex, across six consecutive  
10 three-year periods (1999-2016), were assessed using the National Vital Statistics System in 50 states and  
11 Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27 states in 2015,  
12 examined precipitating circumstances among decedents with and without known MHP.

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
15 half (54.0%) of people did not have a known MHP; 46.0% did. Groups experienced similar and differing  
16 circumstances and some circumstances were common to both. Among people without known MHP, compared  
17 to those with MHP, 45.1% and 39.6% ( $p<.01$ ) had any relationship problems/loss, 54.2% and 49.7% ( $p\leq.01$ ) had  
18 any life stressors/loss and 32.9% and 26.0% ( $p\leq.01$ ) had any recent/impending crises, respectively.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

## 24 INTRODUCTION

### 25 BACKGROUND AND PURPOSE (250/250 words)

26 In 2016, nearly 45,000 suicides (15.6/100,000) occurred in the United States (U.S.), among people ≥10 years old  
27 [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels  
28 [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes to be increasing [1, 4].  
29 Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide, increased  
30 nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation more than \$69  
31 billion in direct medical and work loss costs [1].

32 The *National Strategy for Suicide Prevention*(NSSP) [5] calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor alone, but rather, is multi-determined.  
35 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
36 mental health problems (MHP) [6]. Other contributing factors include social and economic problems, access to  
37 lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills,  
38 and prior suicide attempts [5]. Expanded awareness of the additional circumstances that contribute to suicide  
39 risk apart from MHP, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states

**Comment [BE()]:** Sometimes it is referred to as a 'contributing circumstance' and sometimes its referred to as a 'contributing factor'. I wonder if its best to be consistent so as not to confuse the reader that the two are different. From a plain language perspective, I prefer contributing factors ☺. Also, sometimes it is referred to a just 'contributing factor' while other times it is referred to as 'contributing risk factor'. Also, sometime it is referred to as 'contributing' and sometimes as 'associated'. Should we be consistent?

**I FOUND:**  
CONTRIBUTING CIRCUMSTANCES=3  
PRECIPITATING CIRCUMSTANCES=1  
CIRCUMSTANCES (ALONE)=6  
CONTRIBUTING FACTORS=3  
FACTORS (ALONE)=3  
RISK FACTORS=2

**Comment [za19]:** Is this still accurate?

**Comment [za19]:** Switched the order here

40 in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing  
41 factors, and provides recommendations for multi-level comprehensive suicide prevention.

## 42 **METHODS (255/250 words)**

43 Suicide rates were analyzed for people  $\geq 10$  years only, as attributions of suicidal intent in younger children are  
44 variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death  
45 certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-  
46 X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for  
47 Health Statistics bridged-race population data releases.

48  
49 National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods  
50 from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per  
51 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data  
52 aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends  
53 are reported in terms of average annual percentage changes (AAPCs).

54  
55 Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known  
56 MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death  
57 Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders listed in the Diagnostic and Statistical  
58 Manual of Mental Disorders, Fifth Edition [9]. For this study, alcohol and other substance use disorders were not  
59 defined as MHP, and were examined in both groups. NVDRS aggregates data from three primary data sources:  
60 death certificates, coroner/medical examiner reports (including toxicology), and law enforcement  
61 reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression  
62 analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and  
63 race/ethnicity.

## 64 **RESULTS (584/600 words)**

65 The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2  
66 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except  
67 Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1  
68 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota),  
69 with increases of at least 30% observed in 25 states.

70  
71 Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1).  
72 By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females.  
73 Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was  
74 +1.1% for males and +2.6% for females.

75  
76 Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407). While all  
77 decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known  
78 MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI  
79 = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide  
80 decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9,  
81 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2,  
82 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever  
83 served in the U.S. military.

**Comment [za19]:** The comment made was that it wasn't clear how we defined MHP since substance use disorders are a diagnosis in DSM-V. Changed this to be more straightforward.

**Comment [za19]:** Scott we had this as 0.2 before?? Can you confirm 0.8 is correct?

**Comment [za19]:** Mallia wanted to know if we could say "had served or were serving" in the U.S. Military.

84 Although firearms were used most often, overall (48.5%), decedents with known MHP died by poisoning  
 85 significantly more than those without known MHP (19.8% vs. 10.4%), most frequently by over-the-  
 86 counter/otherwise unclassified (drugs (35.8%), opioids (32.7%), antidepressants (34.6%) or benzodiazepines  
 87 (25.1%).

88 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
 89 circumstances information (Table 3). People without known MHP were 30% less likely to have any substance  
 90 abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental  
 91 health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

92 Decedents without known MHP, versus those with known MHP had a significantly greater likelihood of any  
 93 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
 94 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
 95 were also significantly more likely to have experienced other life stressors, such as criminal-legal problems  
 96 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
 97 the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common crises were  
 98 intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

99 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
 100 those who were recently released, those without a known MHP were significantly more likely to be released  
 101 from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known MHP. Among  
 102 decedents with known MHP recently released from an institution (10.2%), 42.8% were released from psychiatric  
 103 facilities.

104 Decedents without known MHP, compared to those with known MHP, were 60% less likely to have a history of  
 105 suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and 70% less likely to have an attempt history (aOR=0.3, 95% CI=0.3-  
 106 0.3). Both groups disclosed suicide intent frequently, (22.4% vs. 24.5%), respectively.

#### 107 **Conclusions and Comments (680/700 words)**

108 The rise in suicide rates in the overall U.S. has been observed for many years [10]. Reporting of state-specific  
 109 trends overall and by sex is much less common. Similarly, while geographic patterning in suicide rates have  
 110 frequently been reported [10], the current findings point to a disturbing pattern of increases nationwide.  
 111 Understanding the contributing circumstances of suicide is obligatory for prevention practice and decision-  
 112 making.

113 Research and prevention practitioners regularly state that suicide is not caused by a single factor, however, the  
 114 focus of suicide research and prevention practices almost solely focus on MHP. The current study found that  
 115 more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship  
 116 problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.  
 117 This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
 118 deliberation [12].

119 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
 120 half were in current treatment. This suggests that additional supports for this population are needed to keep  
 121 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
 122 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
 123 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems

**Comment [FC]:** I think the comparison group %'s are needed. For instance, drugs (35.8% vs. 35.8%).

I think the presentation of the %'s would be easier here and later on in the results if the p's came out and the text could simply reflect "significant differences" or some variation of indicating in the groups were different.

**I DIDN'T CHANGE THIS B/C IT OPENS UP THE ISSUE OF PEOPLE W/O MHP TAKING ANTIDEP ETC**

**Comment [zaf9]:** I kept this paragraph confined to percentages but did add some additional aOR's in other places.

**Comment [zaf9]:** We were asked to include disclosure of suicide intent. Also, changed the formatting here a bit.

needed that integrate physical and behavioral health and that better support suicide prevention and patient safety, especially through care transitions [11].

Study findings indicate that people with known MHP also experienced other life stressors such as job/financial, relationship, and/or physical health problems. These findings point to the need to both prevent the conditions associated with mental health problems in the first place and the need to support people with known MHP to decrease their risk of poor social, health, and economic outcomes [13].

These results, together, underscore the importance of comprehensive statewide suicide prevention activities that address multiple factors associated with suicide. Prevention strategies may include: strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible, emotional, and social support, and identifying and better supporting people at risk. Other strategies include creating protective environments (e.g., reducing access to lethal means among people at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning and implementing such a comprehensive approach to suicide prevention [14].

These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI, UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS is not yet nationally representative, the 27 states included in the current study represent 49.6% of the U.S. population. Third, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including in-depth interviews with next-of-kin often see greater attributions to MHP and substance abuse disorders, however many methodological variations across studies exist [15]. It is likely that some people without known MHP in the current study were experiencing mental health challenges that were unknown, and hence unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the importance of addressing the range of contributing circumstances.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and prioritize evidence-based comprehensive suicide prevention.

26 friends/family after a suicide occurs.

## 27 INTRODUCTION

### 28 BACKGROUND AND PURPOSE (250/250 words)

29 In 2016, nearly 45,000 suicides (15.6/100,000) occurred in the United States (U.S.), among people ≥10 years old  
30 [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and urbanization levels  
31 [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are to be increasing  
32 [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor for suicide,  
33 increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the nation more  
34 than \$69 billion in direct medical and work loss costs [1].

35 The *National Strategy for Suicide Prevention* (NSSP) [5] calls for a public health approach to suicide prevention  
36 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
37 an approach underscores that suicide is rarely caused by any single factor alone, but rather, is multi-determined  
38 (maybe substitute “multifaceted”). Despite the NSSP guidance, suicide prevention efforts largely focus on  
39 identifying and treating individuals with mental health problems (MHP) [6]. Other contributing factors

**Comment [BE]:** Sometimes it is referred to as a ‘contributing circumstance’ and sometimes its referred to as a ‘contributing factor’. I wonder if its best to be consistent so as not to confuse the reader that the two are different. From a plain language perspective, I prefer contributing factors ☺. Also, sometimes it is referred to a just ‘contributing factor’ while other times it is referred to as ‘contributing risk factor’. Also, sometime it is referred to as ‘contributing’ and sometimes as ‘associated’. Should we be consistent?

**I FOUND:**  
CONTRIBUTING CIRCUMSTANCES=3  
PRECIPITATING CIRCUMSTANCES=1  
CIRCUMSTANCES (ALONE)=6  
CONTRIBUTING FACTORS=3  
FACTORS (ALONE)=3  
RISK FACTORS=2

**Comment [tgs9]:** I think we can say contributing circumstances a few times in the text and then just use circumstances.

**Comment [za19]:** Is this still accurate?

**Comment [tgs9]:** Some editing is needed because this read like the data examined circumstances.

**Comment [za19]:** Switched the order here

**Comment [tgs9]:** I saw that Cory made a good suggestion to say among those with circumstance information. If we make one point about the p-value we can save words. The edits I suggested allow us that there are differences but these are common for both.

**Comment [CA]:** Are we going to have to explain this (...) such as putting in (rate 15.6 per 100,000 population)

**Comment [CA]:** Alternate citation though not quite covering the same yrs - Curtin SC, Warner M, Hedegaard H. Suicide rates for females and males by race and ethnicity: United States, 1999 and 2014. NCHS Health E-Stat. National Center for Health Statistics. April 2016.

circumstances include social and economic problems, access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that contribute to suicide risk apart from MHP, can help reach the nation's goal of reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

#### METHODS (255/250 words)

Suicide rates were analyzed for people  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods from 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [9]. For this study, alcohol and other substance use disorders were not defined as MHP, and were examined in both groups. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

#### RESULTS (584/600 words)

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of at least 30% observed in 25 states.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2,

**Comment [zaf9]:** The comment made was that it wasn't clear how we defined MHP since substance use disorders are a diagnosis in DSM-V. Changed this to be more straightforward.

**Comment [za19]:** Scott we had this as 0.2 before?? Can you confirm 0.8 is correct?

86 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever  
 87 served in the U.S. ~~military~~.

88 Although firearms were used most often, overall (48.5%), decedents with known MHP ~~were more likely to die~~  
 89 ~~by suffocation (31.3 vs. 26.9%) and poisoning (19.8% vs. 10.4%) significantly more~~ than those without known  
 90 MHP (19.8% vs. 10.4%), most frequently by over-the-counter/otherwise unclassified ~~drugs (35.8%), opioids~~  
 91 ~~(32.7%), antidepressants (34.6%) or benzodiazepines (25.1%).~~

92 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
 93 circumstances information (Table 3). People without known MHP were ~~30%~~ less likely to have any substance  
 94 abuse problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental  
 95 health or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

96 ~~Decedents without known MHP, versus those with known MHP had a significantly greater likelihood of any~~  
 97 ~~relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),~~  
 98 ~~arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They~~  
 99 ~~were also significantly more likely to have experienced other life stressors, such as criminal-legal problems~~  
 100 ~~(10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within~~  
 101 ~~the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common crises were~~  
 102 ~~intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.)~~

103 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
 104 those who were recently released (~~5.1%~~), those without a known MHP were significantly more likely to be  
 105 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
 106 MHP. Among decedents with known MHP recently released from an institution (10.2%), 42.8% were released  
 107 from psychiatric facilities.

108 ~~Decedents without known MHP, compared to those with known MHP, were 60% less likely to have a history of~~  
 109 ~~suicidal ideation (aOR=0.4, 95% CI=0.4-0.5) and 70% less likely to have an prior suicide attempt history~~  
 110 ~~(aOR=0.3, 95% CI=0.3-0.3). Both groups disclosed suicide intent frequently, (22.4% vs. 24.5%), respectively.)~~

# 111 Conclusions and Comments (680/700 words)

112 The rise in suicide rates in the overall U.S. has been observed for many years [10]. ~~Reporting of state-specific~~  
 113 ~~trends overall and by sex is much less common.~~ Similarly, while geographic patterning in suicide rates have  
 114 frequently been reported [10], the current findings point to a disturbing pattern of increases nationwide.  
 115 Understanding the contributing circumstances of suicide is obligatory ~~(maybe substitute "essential")~~ for  
 116 prevention practice and decision-making.

117 Researchers and ~~prevention~~-practitioners regularly state that suicide is not caused by a single factor, however,  
 118 the focus of suicide research and prevention practices almost solely focus on MHP. The current study found that  
 119 more than half of suicide decedents in NVDRS did *not* have a known MHP. This group suffered more relationship  
 120 problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.  
 121 This is particularly noteworthy in light of findings that suggest many suicides and attempts occur with minimal  
 122 deliberation [12].

123 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
 124 half were in current treatment. This suggests that additional supports for this population are needed to keep  
 125 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
 126 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to

Comment [zaf9]: Malia wanted to know if we could say "had served or were serving" in the U.S. Military.

Comment [tgs9]: I think that is fine.

Comment [FC()]: I think the comparison group %'s are needed. For instance, drugs (35.8% vs. 35.8%).

I think the presentation of the %'s would be easier here and later on in the results if the p's came out and the text could simply reflect "significant differences" or some variation of indicating in the groups were different.

I DIDN'T CHANGE THIS B/C IT OPENS UP THE ISSUE OF PEOPLE W/O MHP TAKING ANTIDEP ETC

Do we even need to give this distribution? We don't talk about the types in the discussion

Comment [zaf9]: I kept this paragraph confined to percentages but did add some additional aOR's in other places.

Comment [tgs9]: We should be consistent and add this if we have the 10.2% below.

Comment [zaf9]: We were asked to include disclosure of suicide intent. Also, changed the formatting here a bit.

Comment [tgs9]: Why did you add this? It sounds like others have done it already. I think the last version of the start of the conclusion was more compelling.

127 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems  
 128 needed that integrate physical and behavioral health and that better support suicide prevention and patient  
 129 safety, especially through care transitions [11].

130 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
 131 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions  
 132 associated with mental health problems in the first place and the need to support people with known MHP to  
 133 decrease their risk of poor social, health, and economic outcomes [13].

134 These results, together, underscore the importance of comprehensive statewide suicide prevention activities  
 135 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
 136 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
 137 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
 138 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
 139 emotional, and social support, and identifying and better supporting people at risk. Other strategies include  
 140 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
 141 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
 142 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
 143 reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning  
 144 and implementing such a comprehensive approach to suicide prevention [14].

145 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
 146 UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing  
 147 suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS  
 148 is not yet nationally representative, the 27 states included in the current study represent 49.6% of the U.S.  
 149 population. Third, abstractors of NVDRS data are limited to information contained in investigative reports.

150 Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including in-  
 151 depth interviews with next-of-kin often see greater attributions to MHP and substance abuse disorders,  
 152 however many methodological variations across studies exist [15]. It is likely that some people without known  
 153 MHP in the current study were experiencing mental health challenges that were unknown, and hence  
 154 unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the  
 155 importance of addressing the broad range of contributing circumstances.

156 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
 157 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
 158 *Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and  
 159 prioritize evidence-based comprehensive suicide prevention.

Comment [za19]: Is this still accurate?

4 **Structured abstract (245/250 words—this word count is not included in the 1800 max for the remainder)**

5 **Background:** Suicide rates have risen nearly 30% since 1999. Mental health problems (MHP) are just one factor  
6 contributing to suicide. Examining state-level trends in suicide and other contributing circumstances can inform  
7 comprehensive state suicide prevention planning.

8 **Methods:** Trends in age-adjusted suicide rates among people aged ≥10 years, by state and sex, across six  
9 consecutive three-year periods (1999-2016), were assessed using data from the National Vital Statistics System  
10 for 50 states and Washington, D.C (D.C.). Data from the National Violent Death Reporting System, covering 27  
11 states in 2015, were used to examine contributing circumstances among decedents with and without known  
12 MHP.

13 **Results:** From 1999-2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  
14 of 30% or more. Rates increased significantly among males and females, in 34 and 43 states, respectively. Over  
15 half (54.0%) of decedents did *not* have a known MHP. Among decedents with circumstance information, those  
16 without known MHP were more likely (all  $p \leq .01$ ) than those with a MHP to have relationship problems/loss  
17 (45.1% vs 39.6%), life stressors/loss (54.2% vs 49.7%) and recent/impending crises (32.9% vs 26.0%), but these  
18 circumstances were common across groups.

19 **Conclusions:** Suicide rates increased significantly across most states from 1999-2016. Various circumstances  
20 contributed to suicides among people with and without known MHP.

21 **Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach  
22 to prevent suicide risk before it occurs, identify and support people at risk, prevent reattempts, and help  
23 friends/family after a suicide occurs.

## 24 INTRODUCTION

### 25 BACKGROUND AND PURPOSE (255/250 words)

26 In 2016, nearly 45,000 suicides (15.6/100,000 [age-adjusted]) occurred in the United States (U.S.), among people  
27 ≥10 years old [1]. Between 1999 and 2016, suicide rates increased across sexes, racial/ethnic groups, and  
28 urbanization levels [2, 3]. Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that  
29 are *increasing* [1, 4]. Additionally, rates of Emergency Department visits for nonfatal self-harm, a key risk factor  
30 for suicide, increased nearly 45% between 2001 and 2015 [1]. Together, suicides and self-harm injuries cost the  
31 nation more than \$69 billion in direct medical and work loss costs [1].

32 The *National Strategy for Suicide Prevention*(NSSP) [5] calls for a public health approach to suicide prevention  
33 with efforts spanning across multiple levels (i.e., individual, family/relationship, community, and societal). Such  
34 an approach underscores that suicide is rarely caused by any single factor, but rather, is multi-determined.  
35 Despite the NSSP guidance, suicide prevention efforts largely focus on identifying and treating individuals with  
36 mental health problems (MHP) [6]. Other contributing circumstances include social and economic problems,  
37 access to lethal means (e.g., substances, firearms, bridges) among people at risk, poor coping and problem-  
38 solving skills, and prior suicide attempts [5]. Expanded awareness of the additional circumstances that  
39 contribute to suicide risk apart from MHP, and action to address them, can help reach the nation's goal of

reducing suicide rates 20% by 2025 [7]. To assist states in achieving this goal, this study analyzes state-specific trends in suicide rates, assesses the multiple contributing factors, and provides recommendations for multi-level comprehensive suicide prevention.

## **METHODS (256/250 words)**

Suicide rates were analyzed for people aged  $\geq 10$  years only, as attributions of suicidal intent in younger children are variable [8]. Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60-X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999-2016. Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics (Table 2) and circumstances (Table 3) of suicide decedents  $\geq 10$  years, with and without known MHP, were compared in the 27 states with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines MHP as disorders listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [9]. For this study, alcohol and other substance use disorders were not defined as MHP, and were examined in both groups. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known MHP were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## **RESULTS (584/600 words)**

The most recent overall suicide rates (representing 2014-2016) varied four-fold, from 6.9 (D.C.) to 29.2 (Montana) per 100,000 persons per year (Table 1). Across the study period, rates increased in all states, except Nevada (with the 9<sup>th</sup> highest current suicide rate), with absolute increases ranging from +0.8 (Delaware) to +8.1 (Wyoming) per 100,000. Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases more than 30% observed in 25 states.

Modeled suicide rate trends indicated significant increases for 44 states, as well as for the U.S. overall (Table 1). By sex, modeled rate trends indicated significant increases in 34 states for males and in 43 states for females. Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, the national AAPC was +1.1% for males and +2.6% for females.

Suicide decedents without known MHP (N=11,039) were compared to those with MHP (N=9,407). While all decedents were predominately male (Table 2; 76.8%) and non-Hispanic white (83.6%), those without known MHP, relative to those with MHP, were more likely male (83.6% vs. 68.8%; adjusted odds ratio (aOR)=2.3, 95% CI = 2.2-2.5) and racial/ethnic minorities (odds ratio [OR] range: 1.2-2.1; 95% CI range [1.0-1.3] – [1.6-2.0]). Suicide decedents without known MHP also had significantly greater odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2-3.8), of firearm suicide (aOR = 1.6, 95% CI = 1.5-1.7), and of testing positive for alcohol (aOR = 1.2, 95% CI = 1.1-1.3). Among adult decedents, 20.1% and 15.3% of people without and with MHP, respectively, ever served, or were serving, in the U.S. military.

**Comment [za19]:** The comment made was that it wasn't clear how we defined MHP since substance use disorders are a diagnosis in DSM-V. Changed this to be more straightforward.

**Comment [za19]:** Correct definition for military services?

85 Although firearms were used most often, overall (48.5%), decedents with known MHP were more likely to die by  
86 suffocation (31.3 vs. 26.9%) and poisoning (19.8% vs. 10.4%) than those without known MHP .

87 All suicide decedents with known MHP (N=9,407) and approximately 85% without MHP (N=9,357) had available  
88 circumstances information (Table 3). People without known MHP were less likely to have any substance abuse  
89 problems (aOR=0.7, 95% CI=0.7-0.8). While two-thirds of those with known MHP had a history of mental health  
90 or substance abuse treatment (67.2%), just over half (54.0%) were in current treatment.

91 Decedents without known MHP, versus those with known MHP had a significantly greater likelihood of any  
92 relationship problem/loss (45.1% vs. 39.6%), specifically intimate partner problems (30.2% vs. 24.1%),  
93 arguments/conflicts (17.5% vs. 13.6%), and recently perpetrating interpersonal violence (3.0% vs. 1.4%). They  
94 were also significantly more likely to have experienced other life stressors, such as criminal-legal problems  
95 (10.7% vs. 6.2%) or eviction/loss of home (4.3% vs. 3.4%), and they were more likely to have had a crisis within  
96 the preceding or upcoming two weeks (32.9% vs. 26.0%). Among both groups, the most common crises were  
97 intimate partner (36.2% vs. 34.9%) and physical health problems (13.8% vs. 12.9%), respectively.

98 Decedents without known MHP had significantly lower odds of recent release from any institution, but among  
99 those who were recently released (5.1%), those without a known MHP were significantly more likely to be  
100 released from a correctional facility (25.7% vs. 8.7%) or hospital (43.7% vs. 33.0%) than those with a known  
101 MHP. Among decedents with known MHP who were recently released from an institution (10.2%), 42.8% were  
102 released from psychiatric facilities.

103 Decedents without known MHP, compared to those with MHP, were less likely to have a history of suicidal  
104 ideation (aOR=0.4, 95% CI=0.4-0.5) and prior suicide attempt (aOR=0.3, 95% CI=0.3-0.3). Both groups disclosed  
105 suicide intent frequently, (22.4% vs. 24.5%), respectively.

#### 106 Conclusions and Comments (680/700 words)

107 From 1999-2016, 44 states saw significant suicide rate increases. Half of the states experienced increases of 30%  
108 or more. Rates increased significantly in 34 states among males and 43 states among females. More research  
109 into the causes of these trends is necessary [10].

110 Researchers and practitioners regularly state that suicide is not caused by a single factor, however, the focus of  
111 suicide research and prevention practices, almost solely, focus on identify and treating MHP. The current study  
112 found that more than half of suicide decedents in NVDRS did not have a known MHP. This group suffered more  
113 relationship problems and life stressors such as criminal-legal matters, eviction/loss of home, and recent or  
114 impending crises. This is particularly noteworthy in light of findings that suggest many suicides and attempts  
115 occur with minimal deliberation [12].

116 Among people with MHP, two-thirds had a history of mental health and/or substance abuse treatment and over  
117 half were in current treatment. This suggests that additional supports for this population are needed to keep  
118 them safe. This includes broader implementation of affordable and effective treatment modalities such as  
119 doctor-patient collaborative care models and cognitive-behavioral therapy. Additionally, greater access to  
120 behavioral health providers, especially in underserved areas is needed, as is expansion of healthcare systems  
121 needed that integrate physical and behavioral health and that better support suicide prevention and patient  
122 safety, especially through care transitions [11].

123 Study findings indicate that people with known MHP also experienced other life stressors such as job/financial,  
124 relationship, and/or physical health problems. These findings point to the need to both prevent the conditions

Comment [za19]: I kept this paragraph confined to percentages but did add some additional aOR's in other places.

Comment [za19]: We were asked to include disclosure of suicide intent.

Comment [za19]: Thinking to add something here like, This latter finding may indicate that the historical protective effect of being female may be changing.

Comment [za19]: May switch this out if we put in the above statement.

Comment [za19]: Replaced with prior version.

125 associated with mental health problems in the first place and the need to support people with known MHP to  
126 decrease their risk of poor social, health, and economic outcomes [13].

127 These results, together, underscore the importance of comprehensive statewide suicide prevention activities  
128 that address multiple factors associated with suicide. Prevention strategies may include: strengthening  
129 economic supports (e.g., housing stabilization policies, household financial support); teaching coping and  
130 problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in  
131 life; promoting social connectedness to increase a sense of belongingness and access to informational, tangible,  
132 emotional, and social support, and identifying and better supporting people at risk. Other strategies include  
133 creating protective environments (e.g., reducing access to lethal means among people at risk, creating  
134 organizational and workplace policies to promote help-seeking, easing transitions into and out of work for  
135 people with MHP and other life challenges), supporting family and friends after a suicide, and assuring safe  
136 reporting by the media in order to prevent suicide contagion [11]. Some states, such as Colorado, are planning  
137 and implementing such a comprehensive approach to suicide prevention [14].

138 These findings have at least three limitations. In the state-level analysis, rankings for four states (MD, MA, RI,  
139 UT) might have been impacted by large proportions of injury deaths of undetermined intent (i.e. decreasing  
140 suicide rates), or decreased percentages of such deaths over time (i.e. increasing suicide rates). Second, NVDRS  
141 is not yet nationally representative, the 27 states included in the current study represent 49.6% of the U.S.  
142 population. Third, abstractors of NVDRS data are limited to information contained in investigative reports.

143 Therefore, the extent of informant knowledge can impact data completeness and accuracy. Studies including in-  
144 depth interviews with next-of-kin often see greater attributions to MHP (and substance abuse disorders),  
145 however many methodological variations across studies exist [15]. It is likely that some people without known  
146 MHP in the current study were experiencing mental health challenges that were unknown, and hence  
147 unreported by key informants. However, any lack of awareness of decedent MHP suggests, even further, the  
148 importance of addressing the range of contributing circumstances.

149 Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are  
150 available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a*  
151 *Technical Package of Policies, Programs, and Practices* [11] to better understand their suicide problem and  
152 prioritize evidence-based comprehensive suicide prevention.

# Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health problems are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, a total of 54% of decedents in 27 states did not have a known mental health problem. Among decedents with information on circumstances available, several circumstances were significantly more likely among those without known mental health problems than among those with mental health problems, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health problems.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among all age groups younger than 75 years, with the highest percent increases among those aged 45–64 and those aged 10–14 (3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for mental health problems, and preventing reattempts (6). In addition to mental health problems and prior attempts, other circumstances contributing to suicide

Comment [ST]: Delete the “a”

Comment [ST]: Should we add also to help with the transition?

Comment [ST]: Note: font changed. It looks like you ran this for those aged 10+. Is that correct?

Comment [ST]: Did Curtis confirm this cost estimate?

include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance for Suicide Prevention and the American Foundation for Suicide Prevention, ~~and the National Action Alliance of Suicide Prevention~~ of reducing the annual suicide rates ~~by~~ 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health problems, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health problems as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known mental health problems were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity. A range of circumstances have been identified as potential risk factors for suicide. NVDRS only captures relationship problems, life stressors, and recent/imminent crises that were identified as having contributed to the suicide. Decedents could have experienced multiple circumstances.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure 1).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated AAPC for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant AAPC increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

**Comment [ST]:** Check indenting

**Comment [ST]:** What do you think of this shortened version of the text that Katie and you developed? I edited this slightly from what I sent earlier.

We need to make a distinction between these 3 and all the other circumstances in Table 2 because these are linked a contributors but the others might not be.

**Comment [ST]:** This spacing looks odd. Are there options to fix it?

Suicide decedents without known mental health problems (11,039) were compared with those with known mental health problems (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health problems, relative to those with mental health problems, were more likely to be male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health problems also had significantly higher odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health problems and 15.3% of those with mental health problems had ever served, or were currently serving, in the U.S. military.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health problems, decedents without known mental health problems, relative to those with known mental health problems, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Decedents without known mental health problems were less likely to receive toxicology testing. Among those with toxicology results, decedents without known mental health problems were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health problems (n = 9,407) and approximately 85% of those without known mental health problems (n = 9,357) in 27 states (Table 2). Persons without known mental health problems were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health problems. Whereas two thirds of decedents with known mental health problems had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without known mental health problems had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health problems (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health problems were also more likely than were those with known mental health problems to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job/financial problems were commonly contributing stressors among both persons without mental health problems (23.2% and 15.6%, respectively) and those with mental health problems (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group. Similarly, physical health problems and job/financial problems were commonly experienced among both persons without mental health problems (23.2% and 15.6%, respectively) and those with mental health problems (21.4% and 16.8%, respectively).

Decedents without known mental health problems had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health problems but those who were recently released (5.1%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3 24.2% versus 11.6%), than were those recently released with a known mental health problem. Among decedents with known mental health problems who were recently released from an institution (10.1%), 46.7% were released from psychiatric facilities.

**Comment [ST()]:** I'm wondering if we should reverse the order of these because physical and job problem are reported as general stressors and crises. The %'s here are for the overall stressors but the original order seemed to imply that we are describing the crises.

**Comment [HTM()]:** This is the section I found confusing.

**Comment [HTM()]:** So the first number is the % of 5.1% of decedents with no known mental health issue who were recently release.

**CORRECT**

And, the second number is the % of some % of decedents with a known mental health issue who were recently released, correct?

**CORRECT**

As I said on the phone, I had to read several times to figure who was who and where the percentages were coming from.

**I HOPE THESE EDITS HELP CLARIFY NOW.**

**I TOOK OUT THE 5.1% AND DIDN'T INCLUDE THE 10.2% SINCE WE SAY AMONG THOSE RECENTLY RELEASED.**

Maybe something along the lines of below:

Decedents without known mental health problems had significantly lower odds of having been recently released from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released from an institution, decedents without a known mental health issue (5.1%), when compared with those with a known mental health problem (X%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3).

**Comment [ST()]:** Should we drop this %. It is confusing and you don't give the % among those without MHP.

Decedents without known mental health problems were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health problems (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health problems, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. **This finding is consistent with prior research that indicated a decreasing gender gap in male-female suicide rates during 1999–2014 (3).** Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health problems, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health problem, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health problem suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health problems often experienced relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to help persons both manage and prevent the conditions associated with mental health problems in the first place, and to support persons with known mental health problems to decrease their risk for poor outcomes (11). Two thirds of this group with mental health problems had a history of treatment for any mental health or substance use or both, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health problems and other life challenges), supporting family and friends after a suicide, and assuring the media follow safe reporting **recommendations guidelines** (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the

**Comment [ST]:** I thought Scott suggested dropping or reframing this point.

**Comment [ST]:** We should use "recommendations" to be consistent with how these are described

population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health problems in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health problems suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policy, Programs, and Practices (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 deaths were caused by suicide in the United States.

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. Mental health problems often contribute to suicide; however, 2015 data from the National Violent Death Reporting System (27 states) indicate 54% of suicide decedents were not known to have such problems. Other contributors included relationship, substance use, health, and job/financial problems.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing suicide rates 20% by 2025.

**Comment [ST()]:** How about saying "lives were lost to suicide..."

TABLE 1. Selected demographic and descriptive characteristics of suicides among persons aged ≥10 years with and without known mental health problems — National Violent Death Reporting System, 27 states,\* 2015

Characteristic	Total (N = 20,446)	Known mental health problem† (n = 9,407)	No known mental health problem (n = 11,039)	P-value	OR‡ (95% CI)	Adjusted OR† (95% CI)

Abbreviation: CI = confidence interval; OR = odds ratio.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

† Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

‡ OR reflects the risk among those without known mental health problem relative to those with known mental health problem.

§ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health problem was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology tested.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

††† Not significant.

**Abbreviations:** ADD/ADHD = attention deficit disorder/attention deficit hyperactivity disorder; OR = odds ratio; PTSD = posttraumatic stress disorder; SA = substance abuse.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

**Comment [zaf9]:** These four settings should be indented as they are a subset of the recent release from an institution. Recent release should remain unbolded (saying this in case you were to bold it as with other categories) as its part of 'Other life stressors' overarching category.

**Comment [zaf9]:** Same comment as above, these are a subset of the recent crisis within the past or upcoming two weeks and should be indented.

† Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health problem relative to those with known mental health problem.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health problem was the reference group.

\*\* Includes decedents with one or more diagnosed current mental health problems, which are not mutually exclusive. Therefore, sums of percentages for the diagnosed conditions exceed 100%. Denominator includes the number of decedents with one or more current diagnosed mental health problems.

†† Not significant.

§§ Denominator is decedents aged ≥18 years.

¶¶ Denominator is decedents aged 10–18 years.

\*\*\* Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

††† Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

**FIGURE. Percentage change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016<Fig\_Small></Fig\_Small>**

The figure above is a map of the United States showing the percentage change in annual suicide rate, by state, from 1999 to 2016.

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

# Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health problems are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, a total of 54% of decedents in 27 states did not have a known mental health problem. Among decedents with information on circumstances available, several circumstances were significantly more likely among those without a known mental health problems than among those with mental health problems, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health problems.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among all age groups younger than 75 years, with the highest percent increases among those aged 45–64 and those aged 10–14 (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for mental health problems, and preventing reattempts (6). In addition to mental health problems and prior attempts, other circumstances contributing to suicide

include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance for Suicide Prevention and the American Foundation for Suicide Prevention, ~~and the National Action Alliance of Suicide Prevention~~ of reducing the annual suicide rates ~~by~~ 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health problems, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health problems as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent/impending crises) has been identified as potential risk factors for suicide. Circumstances captured by NVDRS are those identified by next of kin as having actively contributed to a person's suicide. Decedents could have experienced multiple circumstances. Decedents with and without known mental health problems were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure 1).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table;

**Comment [ST()]:** This spacing looks odd. Are there options to fix it?

<https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated AAPC for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant AAPC increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health problems (11,039) were compared with those with known mental health problems (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health problems, relative to those with mental health problems, were more likely to be male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health problems also had significantly higher odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged ≥18 years, 20.1% of those without known mental health problems and 15.3% of those with mental health problems had ever served, or were currently serving, in the U.S. military.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health problems, decedents without known mental health problems, relative to those with known mental health problems, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Decedents without known mental health problems were less likely to receive toxicology testing. Among those with toxicology results, decedents without known mental health problems were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health problems (n = 9,407) and approximately 85% of those without known mental health problems (n = 9,357) in 27 states (Table 2). Persons without known mental health problems were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health problems. Whereas two thirds of decedents with known mental health problems had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without known mental health problems had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health problems (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health problems were also more likely than were those with known mental health problems to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job/financial problems were commonly contributing stressors among both persons without mental health problems (23.2% and 15.6%, respectively) and those with mental health problems (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group. Similarly, physical health problems and job/financial problems were commonly experienced among both persons without mental health problems (23.2% and 15.6%, respectively) and those with mental health problems (21.4% and 16.8%, respectively).

Decedents without known mental health problems had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health problems but those who were recently released (5.1%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3 24.2% versus 11.6%), than were

**Comment [HTM()]:** So the first number is the % of 5.1% of decedents with no known mental health issue who were recently release.

Deleted 5.1%

And, the second number is the % of some % of decedents with a known mental health issue who were recently released, correct?

**CORRECT**

As I said on the phone, I had to read several times to figure who was who and where the percentages were coming from.

**I HOPE THESE EDITS HELP CLARIFY NOW.**

**I TOOK OUT THE 5.1% AND DIDN'T INCLUDE THE 10.2% SINCE WE SAY AMONG THOSE RECENTLY RELEASED.**

Maybe something along the lines of below:

Decedents without known mental health problems had significantly lower odds of having been recently released from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released from an institution, decedents without a known mental health issue (5.1%), when compared with those with a known mental health problem (X%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3).

those **recently released** with a known mental health problem, **respectively**. Among decedents with known mental health problems who were recently released from an institution ~~(+10.2%)~~, 46.7% were released from psychiatric facilities.

Decedents without known mental health problems were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health problems (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health problems, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. ~~This finding is consistent with prior research that indicated a decreasing gender gap in male-female suicide rates during 1999–2014 (3).~~ Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health problems, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health problem, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health problem suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health problems often experienced relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to help persons both manage and prevent the conditions associated with mental health problems in the first place, and to support persons with known mental health problems to decrease their risk for poor outcomes (11). Two thirds of this group with mental health problems had a history of treatment for any mental health or substance use or both, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health problems and other life challenges), **strengthening access and deliver of care for people at risk**, supporting family and friends after a suicide, and assuring the media follow safe reporting **recommendations guidelines** (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health problems in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health problems suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policy, Programs, and Practices (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 ~~lives were lost to deaths were caused by~~ suicide in the United States.

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. Mental health problems often contribute to suicide; however, 2015 data from the National Violent Death Reporting System (27 states) indicate 54% of suicide decedents were not known to have such problems. Other contributors included relationship, substance use, health, and job/financial problems.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing suicide rates 20% by 2025.

TABLE 1. Selected demographic and descriptive characteristics of suicides among persons aged ≥10 years with and without known mental health problems — National Violent Death Reporting System, 27 states,\* 2015

The figure above is a map of the United States showing the percentage change in annual suicide rate, by state, from 1999 to 2016.

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

# Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health problems are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, a total of 54% of decedents in 27 states did not have a known mental health problem. Among decedents with information on circumstances available, several circumstances were significantly more likely among those without known mental health problems than among those with mental health problems, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health problems.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among all age groups younger than 75 years, with the highest percent increases among those aged 45–64 and those aged 10–14 (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for mental health problems, and preventing reattempts (6). In addition to mental health problems and prior attempts, other circumstances contributing to suicide

include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance for Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health problems, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health problems as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent/impending crises) has been identified as potential risk factors for suicide. Circumstances captured by NVDRS are those identified by next of kin as having actively contributed to a person's suicide. Decedents could have experienced multiple circumstances. Decedents with and without known mental health problems were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure 1).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated AAPC for the overall suicide rate

was an increase of 1.5%. By sex, estimated national rate trends further indicated significant AAPC increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health problems (11,039) were compared with those with known mental health problems (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health problems, relative to those with mental health problems, were more likely to be male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health problems also had significantly higher odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health problems and 15.3% of those with mental health problems had ever served, or were currently serving, in the U.S. military.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health problems, decedents without known mental health problems, relative to those with known mental health problems, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Decedents without known mental health problems were less likely to receive toxicology testing. Among those with toxicology results, decedents without known mental health problems were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95%, CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health problems ( $n = 9,407$ ) and approximately 85% of those without known mental health problems ( $n = 9,357$ ) in 27 states (Table 2). Persons without known mental health problems were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health problems. Whereas two thirds of decedents with known mental health problems had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without known mental health problems had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health problems (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health problems were also more likely than were those with known mental health problems to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job/financial problems were commonly contributing stressors among both persons without mental health problems (23.2% and 15.6%, respectively) and those with mental health problems (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health problems had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health problems, were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (24.2% versus 11.6%), than those recently released with a known mental health problem, respectively. Among decedents with known mental health problems who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health problems were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health problems (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health problems, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health problems, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health problem, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health problem suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health problems often experienced relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to help persons both manage and prevent the conditions associated with mental health problems in the first place, and to support persons with known mental health problems to decrease their risk for poor outcomes (11). Two thirds of this group with mental health problems had a history of treatment for any mental health or substance use or both, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health problems and other life challenges), strengthening access and delivery of care for people at risk, supporting family and friends after a suicide, and assuring the media follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the

extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health problems in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health problems suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policy, Programs, and Practices (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 lives were lost to suicide in the United States.

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. Mental health problems often contribute to suicide; however, 2015 data from the National Violent Death Reporting System (27 states) indicate 54% of suicide decedents were not known to have such problems. Other contributors included relationship, substance use, health, and job/financial problems.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing suicide rates 20% by 2025.

**Abbreviation:** CI = confidence interval; OR = odds ratio.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

† Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health problems relative to those with known mental health problems.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health problem was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

††† Not significant.

# Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged ≥10 years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases >30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, a total of 54% of decedents in 27 states did not have a known mental health condition. Among decedents with available information, several circumstances were significantly more likely among those without a known mental health condition than among those with mental health condition, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged ≥10 years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates also increased among all age groups younger than 75 years, with the highest percent increases among those aged 10–14 (76% increase [from 1.2 to 2.1 per 100,000 in 1999 and 2016, respectively]) and those aged 45–64 (45% increase [from 13.2 to 19.2 per 100,000 in 1999 and 2016, respectively]). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for mental health conditions, and preventing reattempts.

**Comment [KC():** L1. Please replace "mental health problems" with "mental health conditions" throughout. By definition in methods, these are medical conditions. Calling them "problems" trivializes them and adds further stigma because a person should be able to cope with their problems in our culture. Most are conditions that can be medically treated.

Also, MMWR is a the scientific basis for the fact sheet, and all but the summary box should be written in scientific fashion.

Happy to discuss with author.

**Comment [HTM():** From Michael Iademarco:

L2. Stigmatizing language. I don't want to rock the boat so late in the process. Are these mental health "problems?" I want to be sure we are not using stigmatizing language. How about "conditions?" This occurs throughout the manuscript. In Methods, it seems the data source will support the use of the word conditions and diagnoses.

**Comment [KC():** Mental health condition different than relationship problem, even if both can be devastating.

**Comment [KC():** L3. Find confusing.

**Comment [za9]:** The original ordering here is preferred. The circumstances noted are just three of many. We'd like to highlight the differences between people with and without mental health conditions while at the same time noting that these factors are actually very important to both groups.

**Comment [KC():** Please go through rest of report and change.

**Comment [za9]:** Done!

(6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal established by the American Foundation for Suicide Prevention and the National Action Alliance of Suicide Prevention of reducing suicide rates by 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known mental health conditions were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure 1).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated AAPC-average annual percentage change for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant AAPC-average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

**Comment [KC()]:** L3. Because used only 2 more times, suggest spell throughout.

**Comment [zaf9]:** Removed acronym in all three instances where it appeared.

**Comment [KC()]:** L3. To make it easier for reader, please define abbreviations for states in this table. Some people might not have all 50 abbreviations in their heads.

**Comment [zaf9]:** Will add define abbreviations in the supplementary table.

Suicide decedents without known mental health conditions (11,039) were compared with those with known mental health conditions (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had ever served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health conditions, decedents without known mental health conditions, relative to those with known mental health conditions, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions ( $n = 9,407$ ) and approximately 85% of those without known mental health conditions ( $n = 9,357$ ) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Among all persons with recent crises, intimate partner problems were the most common types and did not differ by group. Similarly, physical health problems and job/financial problems were commonly experienced among both persons without mental health conditions (23.2% and 15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively).

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5), but those who were recently released (5.1%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3), than were those with a known mental health condition. Among decedents with known mental health conditions who were recently released from an institution (10.2%), 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health

conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. This finding is consistent with prior research that indicated a decreasing gender gap in male-female suicide rates during 1999–2014 (3). Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions often experienced relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to help persons both manage and prevent the conditions associated with mental health conditions in the first place, and to support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for any mental health or substance use or both, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk of suicide, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions and other life challenges), supporting family and friends after a suicide, and assuring the media follow safe reporting guidelines (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the

**Comment [KC()]:** L2. Has this been reviewed by a psychiatrist? Not sure what is meant by "prevent the conditions", D?

**Comment [za9]:** This hasn't been reviewed by a psychiatrist but we know that certain circumstances such as adverse childhood experiences are associated with future mental health conditions so we want to also prevent those conditions from occurring in the first place.

**Comment [HTM()]:** Michael Iademarco: L3. MMWR, of self-inflicted injury...

**Comment [za9]:** Prefer to say suicide here vs self-inflicted injury.

extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health conditions in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policies, Programs, and Practices (12) to better understand suicide in their communitiespopulations, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 ~~deaths were caused~~ people died by suicide in the United States. Mental health conditions can contribute to suicide.

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. ~~Mental health problems often contribute to suicide; however,~~ 2015 data from the ~~National Violent Death Reporting System~~ (27 states) indicate 54% of suicide decedents were not known to have mental health conditions. Other contributors included relationship, substance use, health, and job/financial problems, among others.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate ~~suicide rates~~ 20% by 2025.

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, 54% of decedents in 27 states did not have a known mental health condition. Among decedents with available information, several circumstances were significantly more likely among those without a known mental health condition than among those with mental health condition, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (*1*). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (*2,3*). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (*1,4*). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (*1*). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (*1*).

The National Strategy for Suicide Prevention (NSSP) (*5*) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for mental health conditions, and preventing reattempts (*6*). In addition to mental health conditions and prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (*5*). Expanded awareness of these additional

circumstances contributing to suicide risk and action to address them can help reach the national goal established by the American Foundation for Suicide Prevention and the National Action Alliance of Suicide Prevention of reducing suicide rates by 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known mental health conditions were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039) were compared with those with known mental health conditions (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative

to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had ever served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health conditions, decedents without known mental health conditions, relative to those with known mental health conditions, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions ( $n = 9,407$ ) and approximately 85% of those without known mental health conditions ( $n = 9,357$ ) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Among all persons with recent crises, intimate partner problems were the most common types and did not differ by group. Similarly, physical health problems and job/financial problems were commonly experienced among both persons without mental health conditions (23.2% and 15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively).

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5), but those who were recently released (5.1%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3), than were those with a known mental health condition. Among decedents with known mental health conditions who were recently released from an institution (10.2%), 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. This finding is consistent with prior research that indicated a decreasing gender gap in male-female suicide rates during 1999–2014 (3). Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions often experienced relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to help persons both manage and prevent the conditions associated with mental health conditions in the first place, and to support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for any mental health or substance use or both, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk of suicide, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions and other life challenges), supporting family and friends after a suicide, and assuring the media follow safe reporting guidelines (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known

mental health conditions in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policies, Programs, and Practices (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 people died by suicide in the United States. Mental health conditions can contribute to suicide.

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. Other contributors included relationship, substance use, health, and job/financial problems, among others.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

**Abbreviation:** CI = confidence interval; OR = odds ratio.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

† Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology tested.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

††† Not significant.

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health ~~conditions/problems~~ are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged ≥10 years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health ~~conditions/problems~~.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases >30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, a total of 54% of decedents in 27 states did not have a known mental health ~~condition/problem~~. Among decedents with ~~available information on circumstances available~~, several ~~possible contributing circumstances were common among all decedents~~. However, ~~three were~~ significantly more likely among those without a known mental health ~~condition/problems~~ than among those with mental health ~~condition/problems~~, including relationship ~~problems/loss~~ (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%). ~~but these circumstances were common across groups~~.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health problems.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged ≥10 years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a ~~key-main~~ risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for mental health ~~conditions/problems~~, and preventing

**Comment [KC():** L1. Please replace "mental health problems" with "mental health conditions" throughout. By definition in methods, these are medical conditions. Calling them "problems" trivializes them and adds further stigma because a person should be able to cope with their problems in our culture. Most are conditions that can be medically treated.

Also, MMWR is the scientific basis for the fact sheet, and all but the summary box should be written in scientific fashion.

Happy to discuss with author. (b)(6)

(b)(6)

**Comment [HTM():** From Michael Iademarco:

L2. Stigmatizing language. I don't want to rock the boat so late in the process. Are these mental health "problems?" I want to be sure we are not using stigmatizing language. How about "conditions?" This occurs throughout the manuscript. In Methods, it seems the data source will support the use of the word conditions and diagnoses.

**Comment [KC():** Mental health condition different than relationship problem, even if both can be devastating.

**Comment [KC():** L3. Find confusing.

**Comment [KC():** Please go through rest of report and change.

re-attempts (6). In addition to mental health ~~conditions~~ **problems** and prior ~~suicide~~ attempts, other ~~contributing~~ circumstances ~~contributing to suicide~~ include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal established by the American Foundation for Suicide Prevention and the National Action Alliance of Suicide Prevention of reducing suicide rates by 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (**AAPCs**).

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health problems, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health problems as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known mental health problems were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (**Supplementary Table**; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (**Supplementary Table**; <https://stacks.cdc.gov/view/cdc/53785>) (**Figure 4**).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (**Supplementary Table**; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated AAPC for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant AAPC increases for males (1.1%) and females (2.6%) (**Supplementary Table**; <https://stacks.cdc.gov/view/cdc/53785>).

**Comment [KC()]:** L3. Because used only 2 more times, suggest spell throughout.

**Comment [KC()]:** L3. To make it easier for reader, please define abbreviations for states in this table. Some people might not have all 50 abbreviations in their heads.

Suicide decedents without known mental health problems (11,039) were compared with those with known mental health problems (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health problems, relative to those with mental health problems, were more likely to be male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health problems also had significantly higher odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health problems and 15.3% of those with mental health problems had ever served in the U.S. military, or were currently serving at the time of death, in the U.S. military.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health problems, decedents without known mental health problems, relative to those with known mental health problems, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for Decedents without known mental health problems were less likely to receive toxicology testing. Among those with toxicology results, decedents without known mental health problems were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health problems (n = 9,407) and approximately 85% of those without known mental health problems (n = 9,357) in 27 states (Table 2). Persons without known mental health problems were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health problems. Whereas two thirds of decedents with known mental health problems had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in current treatment at the time of death.

Decedents without known mental health problems had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health problems (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health problems were also more likely than were those with known mental health problems to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Among all persons with recent crises, intimate partner problems were the most common types and did not differ by group. Similarly, physical health problems and job/financial problems were commonly experienced among both persons without mental health problems (23.2% and 15.6%, respectively) and those with mental health problems (21.4% and 16.8%, respectively).

Decedents without known mental health problems had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5), but those who were recently released (5.1%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3), than were those with a known mental health problem. Among decedents with known mental health problems who were recently released from an institution (10.2%), 46.7% were released from psychiatric facilities.

Decedents without known mental health problems were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health

problems (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health problems, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. This finding is consistent with prior research that indicated a decreasing gender gap in male-female suicide rates during 1999–2014 (3). Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health problems, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health problem, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health problem suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health problems often experienced relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to help persons both manage and prevent the conditions associated with mental health conditions/problems in the first place, and to support persons with known mental health conditions/problems to decrease their risk for poor outcomes (11). Two thirds of suicide decedents in this group with mental health conditions/problems had a history of treatment for any mental health or substance use or both, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health problems and other life challenges), supporting family and friends after a suicide, and assuring the media follow safe reporting guidelines (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally,

**Comment [KC()]:** L2. Has this been reviewed by a psychiatrist? Not sure what is meant by "prevent the conditions", D?

**Comment [HTM()]:** Michael Iademarco: L3. MMWR, of self-inflicted injury...

abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health problems in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health problems suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policies, Programs, and Practices (12) to better understand and manage their suicide in their communities~~problem~~, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 deaths were caused by suicide in the United States. [Mental health conditions often contribute to suicide.](#)

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. ~~Mental health problems often contribute to suicide; however,~~ 2015 data from ~~the National Violent Death Reporting System~~ (27 states) indicate 54% of suicide decedents were not known to have [mental health conditions](#) ~~such problems~~. Other contributors included relationship, substance use, health, and job/financial problems.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing suicide rates 20% by 2025.

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health problems are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, a total of 54% of decedents in 27 states did not have a known mental health problem. Among decedents with information on circumstances available, several circumstances were significantly more likely among those without a known mental health problems than among those with mental health problems, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health problems.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for mental health problems, and preventing reattempts (6). In addition to mental health problems and prior attempts, other circumstances contributing to suicide include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional

circumstances contributing to suicide risk and action to address them can help reach the national goal established by the American Foundation for Suicide Prevention and the National Action Alliance of Suicide Prevention of reducing suicide rates by 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health problems, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health problems as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known mental health problems were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure 1).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated AAPC for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant AAPC increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health problems (11,039) were compared with those with known mental health problems (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health problems, relative to those with mental health problems, were more likely to be male (83.6% versus 68.8%; odds ratio

(OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health problems also had significantly higher odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health problems and 15.3% of those with mental health problems had ever served, or were currently serving, in the U.S. military.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health problems, decedents without known mental health problems, relative to those with known mental health problems, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Decedents without known mental health problems were less likely to receive toxicology testing. Among those with toxicology results, decedents without known mental health problems were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health problems ( $n = 9,407$ ) and approximately 85% of those without known mental health problems ( $n = 9,357$ ) in 27 states (Table 2). Persons without known mental health problems were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health problems. Whereas two thirds of decedents with known mental health problems had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without known mental health problems had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health problems (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health problems were also more likely than were those with known mental health problems to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Among all persons with recent crises, intimate partner problems were the most common types and did not differ by group. Similarly, physical health problems and job/financial problems were commonly experienced among both persons without mental health problems (23.2% and 15.6%, respectively) and those with mental health problems (21.4% and 16.8%, respectively).

Decedents without known mental health problems had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5), but those who were recently released (5.1%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3), than were those with a known mental health problem. Among decedents with known mental health problems who were recently released from an institution (10.2%), 46.7% were released from psychiatric facilities.

Decedents without known mental health problems were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health problems (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health problems, respectively.

**Comment [HTM()]:** This is the section I found confusing.

**Comment [HTM()]:** So the first number is the % of 5.1% of decedents with no known mental health issue who were recently release.

And, the second number is the % of some % of decedents with a known mental health issue who were recently released, correct?

As I said on the phone, I had to read several times to figure who was who and where the percentages were coming from.

Maybe something along the lines of below:

Decedents without known mental health problems had significantly lower odds of having been recently released from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released from an institution, decedents without a known mental health issue (5.1%), when compared with those with a known mental health problem (X%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment) (aOR = 2.5 95% CI = 1.8–3.3).

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. This finding is consistent with prior research that indicated a decreasing gender gap in male-female suicide rates during 1999–2014 (3). Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health problems, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health problem, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health problem suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health problems often experienced relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to help persons both manage and prevent the conditions associated with mental health problems in the first place, and to support persons with known mental health problems to decrease their risk for poor outcomes (11). Two thirds of this group with mental health problems had a history of treatment for any mental health or substance use or both, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health problems and other life challenges), strengthening access and delivery of care, supporting family and friends after a suicide, and assuring the media follow safe reporting guidelines (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known

mental health problems in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health problems suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policies, Programs, and Practices (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 deaths were caused by suicide in the United States.

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. Mental health problems often contribute to suicide; however, 2015 data from the National Violent Death Reporting System (27 states) indicate 54% of suicide decedents were not known to have such problems. Other contributors included relationship, substance use, health, and job/financial problems.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing suicide rates 20% by 2025.

TABLE 1. Selected demographic and descriptive characteristics of suicides among persons aged ≥10 years with and without known mental health problems — National Violent Death Reporting System, 27 states,\* 2015

Characteristic	Total (N = 20,446)	Known mental health problem† (n = 9,407)	No known mental health problem (n = 11,039)	P-value	OR‡ (95% CI)	Adjusted OR§ (95% CI)

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition. Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health conditions, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among persons in all age groups  $<75$  years, with the highest-largest percent increase (45%; from 13.2 per 100,000 persons [1999] to 19.2 per 100,000 [2016]) and the greatest number of suicides (n=232,108 between 1999 and 2016) occurring among adults aged 45–64 years. s-among those aged 10–14 years (76% increase from 1.2 to 2.1 per 100,000 in 1999 and 2016, respectively) and those aged 45–64 years a(45% increase from 13.2 to 19.2 per 100,000 in 1999 and 2016, respectively) (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but

rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on mental health conditions alone by identifying suicidal persons, providing treatment for mental health conditions, and preventing reattempts (6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years ~~only~~, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (*i.e.*, relationship problems, life stressors, and recent or impending crises) ~~has~~ been identified as potential risk factors for suicide. Circumstances captured by NVDRS are those identified by next of kin as having actively contributed to a person's suicide. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039) were compared with those with known mental health conditions (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide followed by -suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged ≥18 years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had ever served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health conditions, decedents without known mental health conditions, relative to those with known mental health conditions, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions (n = 9,407) and approximately 85% of those without known mental health conditions (n = 9,357) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence in the past month (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and ~~job~~ financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and 15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely than decedents with mental health conditions to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or

other facility (e.g., alcohol/substance treatment) (24.2% versus 11.6%) ~~than were those recently released with a known mental health condition.~~ Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

**Comment [za9]:** Should this be two sets of parentheses or just one?

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward ~~mental health conditions alone vis-à-vis~~ downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions ~~also~~ often experienced ~~nonmental health factors such as~~ relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to ~~both help persons manage mental health conditions and to~~ prevent the circumstances associated with their onset ~~of mental health conditions in the first place, as well and~~ support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for ~~any~~ mental health ~~and/or~~ substance ~~use or both disorders~~, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk of suicide, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions and other life challenges), strengthening access and delivery of care ~~for persons at risk~~, supporting family and friends after a suicide, and assuring the media follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health conditions in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policy, Programs, and Practices (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 persons died by suicide in the United States. Mental health conditions can contribute to suicide.

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. Other contributors included relationship, substance use, health, and job or financial problems, among others.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

† Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

# Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

## Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are just one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition. Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health condition, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among persons in all age groups  $<75$  years, with the highest percent increases among those aged 10–14 years (76% increase from 1.2 to 2.1 per 100,000 in 1999 and 2016, respectively) and those aged 45–64 years (45% increase from 13.2 to 19.2 per 100,000 in 1999 and 2016, respectively) (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on

identifying suicidal persons, providing treatment for mental health conditions, and preventing reattempts (6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent or impending crises) have been identified as potential risk factors for suicide. Circumstances captured by NVDRS are those identified by next of kin as having actively contributed to a person's suicide. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039) were compared with those with known mental health conditions (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide-suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had ever served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health conditions, decedents without known mental health conditions, relative to those with known mental health conditions, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions ( $n = 9,407$ ) and approximately 85% of those without known mental health conditions ( $n = 9,357$ ) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (54.2% versus 49.7%) such as criminal/legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job or financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and 15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment)

(24.2% versus 11.6%), than were those recently released with a known mental health condition. Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions often experienced relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to help persons manage mental health conditions and to prevent the circumstances associated with their onset, as well support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for any mental health or substance use or both, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk of suicide, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions and other life challenges), strengthening access and delivery of care for persons at risk, supporting family and friends after a suicide, and assuring the media follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large

proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health conditions in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's Preventing Suicide: a Technical Package of Policy, Programs, and Practices (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

## Summary

### What is already known about this topic?

In 2016, nearly 45,000 persons died by suicide in the United States. Mental health conditions can contribute to suicide.

### What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. Other contributors included relationship, substance use, health, and job or financial problems, among others.

### What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

§ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health condition was the reference group.

\*\* Includes decedents with one or more diagnosed current mental health conditions, which are not mutually exclusive. Therefore, sums of percentages for the diagnosed conditions exceed 100%. Denominator includes the number of decedents with one or more current diagnosed mental health conditions.

†† Denominator is decedents aged  $\geq 18$  years.

§§ Denominator is decedents aged 10–18 years.

¶¶ Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

\*\*\* Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

**FIGURE. Percentage change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016<Fig\_Small></Fig\_Small>**

The figure above is a map of the United States showing the percentage change in annual suicide rate, by state, from 1999 to 2016.

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

## **Vital Signs: Trends in State Suicide Rates — United States, 1999–2016 and Circumstances Contributing to Suicide — 27 States, 2015**

Deborah M. Stone, ScD<sup>1</sup>; Thomas R. Simon PhD<sup>1</sup>; Katherine A. Fowler, PhD<sup>1</sup>; Scott R. Kegler, PhD<sup>2</sup>; Keming Yuan, MS<sup>1</sup>; Kristin M. Holland, PhD<sup>1</sup>; Asha Z. Ivey-Stephenson, PhD<sup>1</sup>; Alex E. Crosby, MD<sup>1</sup>

**Background:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health problems are just one factor contributing to suicide. Examining state-level trends in, and the multiple circumstances contributing to, suicide can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive three-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia (DC). Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health problems.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases of more than 30%. Rates increased significantly among males and females in 34 and 43 states, respectively. In 2015, more than half (54%) of decedents in 27 states did not have a known mental health problem. Among decedents with circumstance information available, several circumstances were significantly more likely among those without a known mental health problems than among those with mental health problems, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health problems.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family in the aftermath of a suicide.

## **Introduction**

### **Background and Purpose**

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). Between 1999 and 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide is the 10<sup>th</sup> leading cause of death and is one of just three leading causes that are increasing (1,4).

Additionally, rates of emergency department visits for nonfatal self-harm, a key risk factor for suicide, increased 42% between 2001 and 2016 (1). Together, suicides and self-harm injuries cost the nation more than \$69 billion in direct medical and work loss costs (1).

The *National Strategy for Suicide Prevention (NSSP)* (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (i.e., individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite the NSSP guidance, suicide prevention largely focuses on identifying suicidal persons, providing treatment for mental health problems, and preventing reattempts (6). In addition to mental health problems and prior attempts, other circumstances contributing to suicide include social and economic

problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the nation's goal of reducing suicide rates by 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multi-level comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years only, as determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases 10<sup>th</sup> Revision*, underlying-cause-of death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive three-year aggregate periods spanning 1999–2016 (1999–2001, 2002–2004; 2005–2007; 2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. year 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same three-year data aggregates, employing weighted least squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes (AAPCs).

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health problems, and the circumstances surrounding the suicides were compared in the 27 states

with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health problems as disorders and syndromes listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. Decedents with and without known mental health problems were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios with 95% confidence intervals (CI), controlling for age group, sex, and race/ethnicity.

## **Results**

The most recent overall suicide rates (representing 2014–2016) varied four-fold, from 6.9 (DC) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from +0.8 per 100,000 (Delaware) to +8.1 (Wyoming). Percentage increases in rates ranged from +5.9% (Delaware) to +57.6% (North Dakota), with increases of more than 30% observed in 25 states (Supplementary Table) (Figure 1).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table).

Nationally, the model-estimated AAPC for the overall suicide rate was +1.5%. By sex, estimated national rate trends further indicated significant increases for males (AAPC +1.1%) and females (AAPC +2.6%) (Supplementary Table).

Suicide decedents without known mental health problems (N = 11,039) were compared with those with known mental health problems (N = 9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health problems, relative to those with mental health problems, were more likely male (83.6% versus 68.8%; odds ratio (OR) = 2.3, 95% CI = 2.2–2.5) and racial/ethnic minorities (OR range: 1.2–2.0). Suicide decedents without known mental health problems also had significantly higher odds of perpetrating homicide-suicide (adjusted odds ratio (aOR) = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health problems and 15.3% of those with mental health problems had ever served, or were currently serving, in the U.S. military.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health problems, decedents without known mental health problems, relative to those with known mental health problems, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

Decedents without known mental health problems were less likely to receive toxicology testing. Among those with toxicology results, decedents without known mental health problems were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health problems (N = 9,407) and approximately 85% of those without known mental health

problems (N = 9,357) in 27 states (Table 2). Persons without known mental health problems were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health problems. Whereas two thirds of decedents with known mental health problems had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in current treatment.

Decedents without known mental health problems had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health problems (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and recently perpetrating interpersonal violence (3.0% versus 1.4%). Decedents without known mental health problems were also more likely than were those with known mental health problems to have experienced any life stressors (54.2% versus 49.7%) such as criminal-legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Among all persons with recent crises, intimate partner problems were the most common types and did not differ by group. Similarly, physical health problems and job/financial problems were commonly experienced among both persons without mental health problems (23.2% and 15.6%, respectively) and those with mental health problems (21.4% and 16.8%, respectively).

Decedents without known mental health problems had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5), but those who were recently released (5.1%), were significantly more likely to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility (e.g., alcohol/substance treatment)

(aOR = 2.5 95% CI = 1.8–3.3), than were those with a known mental health problem. Among decedents with known mental health problems who were recently released from an institution (10.2%), 46.7% of were released from psychiatric facilities.

**Comment [OADS]:** Please delete the extra preposition. Level 3.

**Comment [HTM():]** I have already corrected.

Decedents without known mental health problems were significantly less likely to have a history of suicidal ideation (23.0%) or prior suicide attempts (10.3%) compared with those with known mental health problems (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health problems, respectively.

### Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases of more than 30%. Rates increased significantly among males in 34 states, and females, in 43 states. This finding is consistent with prior research showing a decreasing gender gap in male-female suicide rates during 1999–2014 (3). Additional research into the specific causes of these trends is necessary. Data from the 27 states participating in NVDRS provides important insight into circumstances surrounding suicide and can help states identify prevention priorities. Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often oriented toward downstream identification of suicidal persons, treatment of mental health problems and prevention of reattempts. This study found that more than half of suicide decedents in NVDRS did not have a known mental health problems, indicating that additional focus on non-mental health factors, further upstream, is essential to a public health approach (10). This group suffered more from relationship problems and other life stressors such as criminal-legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health problems often experienced relationship problems and other life stressors such as job/financial and/or physical health problems. These findings point to the need to both help persons manage and prevent the conditions associated with mental health problems in the first place, and to support persons with known mental health problems to decrease their risk of poor outcomes (11). Two thirds of this group had a history of any mental health and/or substance use treatment, with over half in treatment when they died. This suggests the need for additional safety supports, including broader implementation of affordable and effective treatment modalities such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. Additionally, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health problems) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health problems and other life challenges), supporting family and friends after a suicide, and assuring safe reporting by the

media in order to prevent suicide contagion (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

**Comment [OADS]:** Please elaborate to explain this strategy, e.g. the meaning of "safe reporting" and "suicide contagion." Please revise or respond.  
Level 2

The findings in this report are subject to at least three limitations. In the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward), or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population

(<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally,

abstractors of NVDRS data are limited to information contained in investigative reports.

Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies including more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations across studies exist (14). It is likely that some persons without known mental health problems in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants.

Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health problems suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NVDRS and resources such as CDC's *Preventing Suicide: a Technical Package of Policies, Programs, and Practices* (12) to better understand their suicide problem, prioritize evidence-based comprehensive suicide prevention, and save lives.

## **Summary**

### **What is already known about this topic?**

In 2016, nearly 45,000 deaths were caused by suicide in the United States.

### **What is added by this report?**

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. Mental health problems often contribute to suicide; however, 2015 data from the National Violent Death Reporting System (27 states) indicate 54% of suicide decedents were not known to have such problems. Other contributors included relationship, substance use, health, and job/financial problems.

### **What are the implications for public health practice?**

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing suicide rates 20% by 2025.

**Abbreviation:** CI = confidence interval.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health problem in coroner/medical examiner or law enforcement reports.

<sup>§</sup> Odds ratio reflects the risk among those without known mental health problem relative to those with known mental health problem.

<sup>¶</sup> Logistic regression was used to estimate adjusted odds ratio with 95% CIs after controlling for age, sex, race and ethnicity. Known mental health problem was used as the reference group.

<sup>\*\*</sup> Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

<sup>††</sup> Denominator is decedents aged ≥18 years with reported military service status.

<sup>§§</sup> Denominator is decedents who died by poisoning, including overdose.

<sup>¶¶</sup> Denominator is decedents with any toxicology tested.

<sup>\*\*\*</sup> Denominator for each positive group is the number tested for the substance in that group.

### Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are one of several factors contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34 and 43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition.

Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health conditions, including relationship problems/loss (45.1% versus 39.6%), life stressors (50.5% versus 47.2%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanized areas (2,3). Suicide rates have also increased among persons in all age groups  $< 75$  years, with adults aged 45–64 having the largest percent increase (45%; from 13.2 per 100,000 persons [1999] to 19.2 per 100,000 [2016]) and the greatest number of suicides (232,108 from 1999 to 2016) (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$70 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on mental health conditions alone by identifying suicidal persons, providing treatment for mental health conditions, and preventing reattempts (6). In addition to mental health conditions and prior suicide attempts, other contributing circumstances

include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for strategies to include in comprehensive suicide prevention efforts that are based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years because determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007;

2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

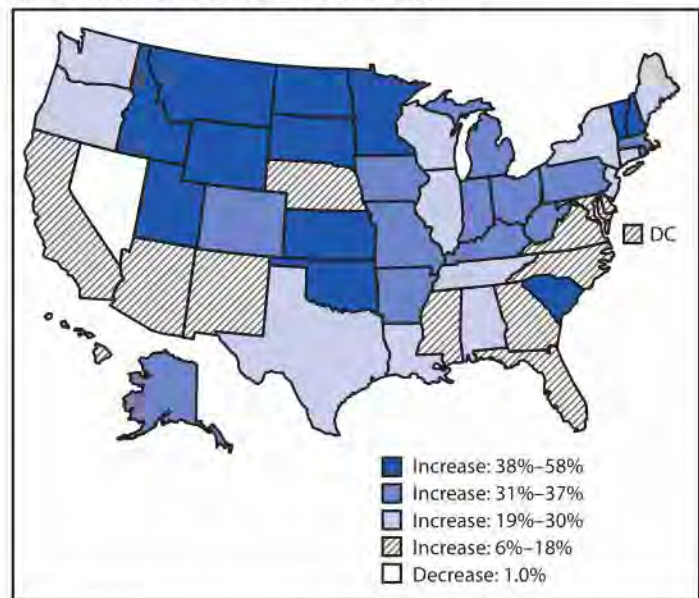

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of problematic alcohol and other substance use that is captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent or impending crises) have been identified as potential risk factors for suicide. Circumstances captured by NVDRS are those identified as contributing to suicide in coroner/medical examiner or law enforcement reports, which reflect information provided by family and friends. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table;

**FIGURE. Percent change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016**

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

<https://stacks.cdc.gov/view/cdc/53785>). Nationally, the model-estimated average annual percentage change for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039; 54%) were compared with those with known mental health conditions (9,407; 46%) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio [OR] = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide followed by suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had ever served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%), decedents without known mental health conditions were more likely to die by firearm (55.3%) and less likely to die by hanging/strangulation/suffocation (26.9%) or poisoning (10.4%) than were those with known mental health conditions (40.6%, 31.3%, and 19.8%, respectively). These differences remained significant in the adjusted models.

See table footnotes on next page.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions (n = 9,407) and approximately 85% of those without known mental health conditions (n = 9,357) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any problematic substance use (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and perpetrating interpersonal violence in the past month (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (50.5% versus 47.2%) such as criminal legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job/financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and

† Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely than decedents with mental health problems to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility, such as an alcohol/substance use treatment facility (24.2% versus 11.6%). Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation

(23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often

oriented toward mental health conditions alone with regard to downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions also often experienced other factors such as relationship problems and other life stressors such as job/financial or physical health problems that contributed to their suicide. These findings point to the need to both prevent the circumstances associated with the onset of mental health conditions in the first place and support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for mental health or substance use disorders, with approximately half in treatment when they died. This finding suggests the

need for additional safety supports, including broader implementation of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk for suicide, creating organizational and workplace policies to promote help-seeking, easing transitions

into and out of work for persons with mental health conditions and other life challenges), strengthening access and delivery of care, supporting family and friends after a suicide, and assuring the media follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).

The findings in this report are subject to at least three limitations. First, in the state-level analysis, rankings for four states (Maryland, Massachusetts, Rhode Island, and Utah) might have been affected by large proportions of injury deaths of undetermined intent (potentially biasing reported suicide rates downward) or decreased percentages of such deaths over time (potentially biasing estimated rate trends upward). Second, NVDRS is not yet nationally representative; the 27 states included represent 49.6% of the population (<https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml>). Finally, abstractors of NVDRS data are limited to information contained in investigative reports. Therefore, the extent of informant knowledge can affect data completeness and accuracy. Studies that include more in-depth interviews with next-of-kin often identify greater attributions to mental disorders (13); however, many methodological variations

## References

## Summary

## What is already known about this topic?

In 2016, nearly 45,000 persons died by suicide in the United States. Mental health conditions are one of several contributors to suicide.

## What is added by this report?

During 1999–2016, suicide rates increased in nearly every state, including >30% increases in 25 states. 2015 data from 27 states indicate 54% of suicide decedents were not known to have mental health conditions. ~~Other contributors included relationship, substance use, health, and job or financial problems; among others.~~

## What are the implications for public health practice?

A comprehensive approach using proven prevention strategies, such as those in CDC's Technical Package for Suicide Prevention, can help reach the national goal of reducing the annual suicide rate 20% by 2025.

across studies exist (14). It is likely that some persons without known mental health conditions in the current study were experiencing mental health challenges that were unknown, and hence underreported by key informants. Nonetheless, the high prevalence of diverse contributing circumstances among those with and without known mental health conditions suggests the importance of addressing the broad range of factors that contribute to suicide.

Suicide is a growing public health problem. Effective approaches to prevent the many suicide risk factors are available. States and communities can use data from NEDRS and resources such as CDC's Preventing Suicide: A Technical Package of Policy, Programs, and Practices (12) to better understand suicide in their populations, prioritize evidence-based comprehensive suicide prevention, and save lives.

### Abstract

**Introduction:** Suicide rates in the United States have risen nearly 30% since 1999, and mental health conditions are ~~just~~ one factor contributing to suicide. Examining state-level trends in suicide and the multiple circumstances contributing to it can inform comprehensive state suicide prevention planning.

**Methods:** Trends in age-adjusted suicide rates among persons aged  $\geq 10$  years, by state and sex, across six consecutive 3-year periods (1999–2016), were assessed using data from the National Vital Statistics System for 50 states and the District of Columbia. Data from the National Violent Death Reporting System, covering 27 states in 2015, were used to examine contributing circumstances among decedents with and without known mental health conditions.

**Results:** During 1999–2016, suicide rates increased significantly in 44 states, with 25 states experiencing increases  $>30\%$ . Rates increased significantly among males and females in 34  43 states, respectively. Fifty-four percent of decedents in 27 states in 2015 did not have a known mental health condition.

Among decedents with available information, several circumstances were significantly more likely among those without known mental health conditions than among those with mental health conditions, including relationship problems/loss (45.1% versus 39.6%), life stressors (54.2% versus 49.7%), and recent/impending crises (32.9% versus 26.0%), but these circumstances were common across groups.

**Conclusions:** Suicide rates increased significantly across most states during 1999–2016. Various circumstances contributed to suicides among persons with and without known mental health conditions.

**Implications for Public Health Practice:** States can use a comprehensive evidence-based public health approach to prevent suicide risk before it occurs, identify and support persons at risk, prevent reattempts, and help friends and family members in the aftermath of a suicide.

## Introduction

In 2016, nearly 45,000 suicides (15.6/100,000 population [age-adjusted]) occurred in the United States among persons aged  $\geq 10$  years (1). From 1999 to 2015, suicide rates increased among both sexes, all racial/ethnic groups, and all urbanization levels (2,3). Suicide rates have also increased among persons in all age groups  $< 75$  years, with the largest percent increase (45%; from 13.2 per 100,000 persons [1999] to 19.2 per 100,000 [2016]) and the greatest number of suicides (232,108 from 1999 to 2016) occurring among adults age 45–65 years (1,3). Suicide is the 10th leading cause of death and is one of just three leading causes that are increasing (1,4). In addition, rates of emergency department visits for nonfatal self-harm, a main risk factor for suicide, increased 42% from 2001 to 2016 (1). Together, suicides and self-harm injuries cost the nation approximately \$69 billion in direct medical and work loss costs (1).

The National Strategy for Suicide Prevention (NSSP) (5) calls for a public health approach to suicide prevention with efforts spanning multiple levels (individual, family/relationship, community, and societal). Such a comprehensive approach underscores that suicide is rarely caused by any single factor, but rather, is determined by multiple factors. Despite NSSP guidance, suicide prevention largely focuses on mental health conditions alone by identifying suicidal persons, providing treatment for mental health conditions, and preventing reattempts (6). In addition to mental health conditions and

prior suicide attempts, other contributing circumstances include social and economic problems, access to lethal means (e.g., substances, firearms) among persons at risk, and poor coping and problem-solving skills (5). Expanded awareness of these additional circumstances contributing to suicide risk and action to address them can help reach the national goal, established by the National Action Alliance of Suicide Prevention and the American Foundation for Suicide Prevention, of reducing the annual suicide rate 20% by 2025 (7). To assist states in achieving this goal, CDC analyzed state-specific trends in suicide rates and assessed the multiple contributing factors to suicide; this report presents options for multilevel, comprehensive suicide prevention based on the best available evidence.

## Methods

Suicide rates were analyzed for persons aged  $\geq 10$  years because determining suicidal intent in younger children can be difficult (8). Age-specific suicide counts were tabulated based on National Vital Statistics System coded death certificate records (*International Classification of Diseases, Tenth Revision*, underlying-cause-of-death codes X60–X84, Y87.0, U03). Age-specific population estimates were obtained from U.S. Census Bureau/National Center for Health Statistics bridged-race population data releases.

National and state-level suicide rate estimates were calculated for six consecutive 3-year aggregate periods spanning 1999–2016 (1999–2001; 2002–2004; 2005–2007;

2008–2010; 2011–2013; and 2014–2016). Rate estimates were age-adjusted to the U.S. 2000 standard population and expressed per 100,000 persons per year. Age-adjusted suicide rate trends were modeled using the same 3-year data aggregates, employing weighted least-squares regression with inverse-variance weighting. Modeled rate trends are reported in terms of average annual percentage changes.

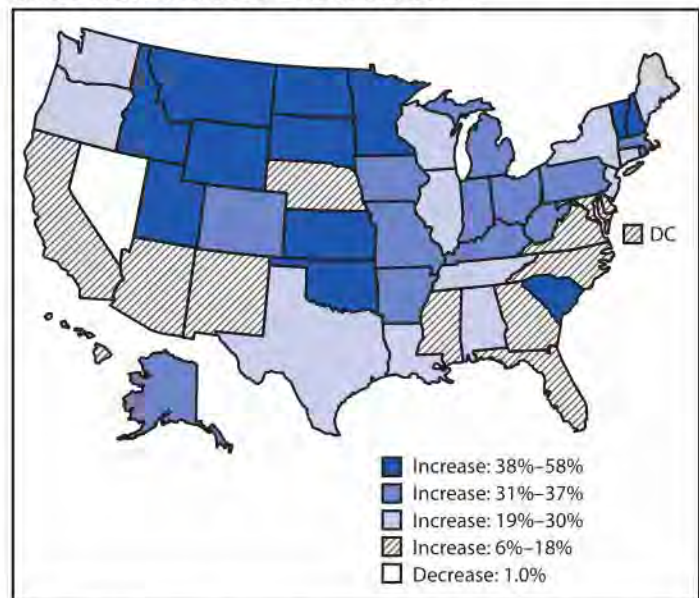

Characteristics of persons aged  $\geq 10$  years who died by suicide, with and without known mental health conditions, and the circumstances surrounding the suicides were compared in the 27 states\* with complete data participating in CDC's National Violent Death Reporting System (NVDRS) in 2015. NVDRS defines mental health conditions as disorders and syndromes listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (9), with the exception of alcohol and other substance use disorders, which are captured separately in NVDRS. NVDRS aggregates data from three primary data sources: death certificates, coroner/medical examiner reports (including toxicology), and law enforcement reports. A range of circumstances (relationship problems, life stressors, and recent or impending crises) have been identified as potential risk factors for suicide. Circumstances captured by NVDRS are those identified by next of kin as having actively contributed to a person's suicide. Decedents could have experienced multiple circumstances. Decedents with and without known mental health conditions were compared using Chi-square tests. Logistic regression analyses estimated adjusted odds ratios (aORs) with 95% confidence intervals (CIs), controlling for age group, sex, and race/ethnicity.

## Results

The most recent overall suicide rates (representing 2014–2016) varied fourfold, from 6.9 (District of Columbia) to 29.2 (Montana) per 100,000 persons per year (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Across the study period, rates increased in all states except Nevada (where the rate was consistently high throughout the study period), with absolute increases ranging from 0.8 per 100,000 (Delaware) to 8.1 (Wyoming). Percentage increases in rates ranged from 5.9% (Delaware) to 57.6% (North Dakota), with increases  $>30\%$  observed in 25 states (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>) (Figure).

Modeled suicide rate trends indicated significant increases in 44 states, among males (34 states) and females (43 states), as well as for the United States overall (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>). Nationally, the

**FIGURE. Percent change in annual suicide rate,\* by state — United States, from 1999–2001 to 2014–2016**

\* Per 100,000 population, age-adjusted to the 2000 U.S. standard population.

model-estimated average annual percentage change for the overall suicide rate was an increase of 1.5%. By sex, estimated national rate trends further indicated significant average annual percentage change increases for males (1.1%) and females (2.6%) (Supplementary Table; <https://stacks.cdc.gov/view/cdc/53785>).

Suicide decedents without known mental health conditions (11,039) were compared with those with known mental health conditions (9,407) in 27 states. Whereas all decedents were predominately male (76.8%) (Table 1) and non-Hispanic white (83.6%), those without known mental health conditions, relative to those with mental health conditions, were more likely to be male (83.6% versus 68.8%; odds ratio [OR] = 2.3, 95% CI = 2.2–2.5) and belong to a racial/ethnic minority (OR range = 1.2–2.0). Suicide decedents without known mental health conditions also had significantly higher odds of perpetrating homicide followed by suicide (aOR = 2.9, 95% CI = 2.2–3.8). Among adult decedents aged  $\geq 18$  years, 20.1% of those without known mental health conditions and 15.3% of those with mental health conditions had ever served in the U.S. military or were serving at the time of death.

Whereas firearms were the most common method of suicide overall (48.5%) and among decedents with and without mental health conditions, decedents without known mental health conditions, relative to those with known mental health conditions, were more likely to die by firearm (55.3% versus 40.6%) and less likely to die by hanging/strangulation/suffocation (26.9% versus 31.3%) or poisoning (10.4% versus 19.8%). These differences remained significant in the adjusted models.

See table footnotes on next page.

Toxicology testing was less likely to be performed for decedents without known mental health conditions. Among those with toxicology results, decedents without known mental health conditions were less likely to test positive for any substance overall (aOR = 0.8, 95% CI = 0.7–0.8), including opioids (aOR = 0.90, 95% CI = 0.81–0.99), but were more likely to test positive for alcohol (aOR = 1.2, 95% CI = 1.1–1.3).

Information on circumstances surrounding suicide were available for all decedents with mental health conditions (n = 9,407) and approximately 85% of those without known mental health conditions (n = 9,357) in 27 states (Table 2). Persons without known mental health conditions were less likely to have any substance use disorders (aOR = 0.7, 95% CI = 0.7–0.8) than were persons with known mental health conditions. Whereas two thirds of decedents with known mental health conditions had a history of mental health or substance use treatment (67.2%), just over half (54.0%) were in treatment at the time of death.

Decedents without known mental health conditions had a significantly higher likelihood of any relationship problem/loss (45.1%) than did those with known mental health conditions (39.6%), specifically intimate partner problems (30.2% versus 24.1%), arguments/conflicts (17.5% versus 13.6%), and perpetrating interpersonal violence in the past month (3.0% versus 1.4%). Decedents without known mental health conditions were also more likely than were those with known mental health conditions to have experienced any life stressors (54.2% versus 49.7%) such as criminal legal problems (10.7% versus 6.2%) or eviction/loss of home (4.3% versus 3.4%) and were more likely to have had a recent or impending (within the preceding or upcoming 2 weeks, respectively) crisis (a current or acute event thought to contribute to the suicide) (32.9% versus 26.0%). All of these differences remained significant in the adjusted models. Physical health problems and job/financial problems were commonly contributing stressors among both persons without mental health conditions (23.2% and

† Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

§ OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

¶ Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health condition was used as the reference group.

\*\* Decedents were aged ≥10 years, as per standard in the suicide prevention literature.

†† Denominator is decedents aged ≥18 years with reported military service status.

§§ Denominator is decedents who died by poisoning, including overdose.

¶¶ Denominator is decedents with any toxicology testing.

\*\*\* Denominator for each positive group is the number tested for the substance in that group.

15.6%, respectively) and those with mental health conditions (21.4% and 16.8%, respectively). Similarly, among all persons with recent crises, intimate partner problems were the most common types and did not differ by group.

Decedents without known mental health conditions had significantly lower odds of recent release from any institution (aOR = 0.5, 95% CI = 0.4–0.5). Among those recently released, decedents without known mental health conditions were significantly more likely than decedents with mental health problems to have been released from a correctional facility (25.7% versus 8.7%), hospital (43.7% versus 33.0%), or other facility, such as an alcohol/substance use treatment facility (24.2% versus 11.6%). Among decedents with known mental health conditions who were recently released from an institution, 46.7% were released from psychiatric facilities.

Decedents without known mental health conditions were significantly less likely to have a history of suicidal ideation

(23.0%) or prior suicide attempts (10.3%) compared with those with known mental health conditions (40.8% and 29.4%, respectively). Suicide intent was disclosed by 22.4% and 24.5% of persons without and with known mental health conditions, respectively.

## Conclusions and Comments

During 1999–2016, suicide rates increased significantly in 44 states, and 25 states experienced increases >30%. Rates increased significantly among males in 34 states, and females in 43 states. Additional research into the specific causes of these trends is needed. Data from the 27 states participating in NVDRS provide important insight into circumstances surrounding suicide and can help states identify prevention priorities.

Suicidologists regularly state that suicide is not caused by a single factor (5); however, suicide prevention is often

oriented toward mental health conditions alone with regard to downstream identification of suicidal persons, treatment of mental health conditions, and prevention of reattempts. This study found that approximately half of suicide decedents in NVDRS did not have a known mental health condition, indicating that additional focus on nonmental health factors further upstream could provide important information for a public health approach (10). Those without a known mental health condition suffered more from relationship problems and other life stressors such as criminal/legal matters, eviction/loss of home, and recent or impending crises.

Similarly, persons with mental health conditions also often experienced nonmental health factors such as relationship problems and other life stressors such as job/financial or physical health problems. These findings point to the need to both prevent the circumstances associated with the onset of mental health conditions in the first place and support persons with known mental health conditions to decrease their risk for poor outcomes (11). Two thirds of suicide decedents with mental health conditions had a history of treatment for mental health or substance use disorders, with approximately half in treatment when they died. This finding suggests the need for additional safety supports, including broader implementation

**TABLE 2. (Continued) Circumstances preceding suicide among decedents aged  $\geq 10$  years with and without known mental health conditions — National Violent Death Reporting System, 27 states,\* 2015**

Characteristic	Total	Known mental health condition <sup>†</sup> no. (%)	No known mental health condition no. (%)	P-value	OR <sup>§</sup> (95% CI)	Adjusted OR <sup>¶</sup> (95% CI)

**Abbreviations:** ADD/ADHD = attention deficit disorder/attention deficit hyperactivity disorder; CI = confidence interval; N/A = not applicable; NS = not significant; OR = odds ratio; PTSD = posttraumatic stress disorder; SA = substance abuse.

\* Alaska, Arizona, Colorado, Connecticut, Georgia, Hawaii, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, Utah, Vermont, Virginia, and Wisconsin.

<sup>†</sup> Decedent had been identified as having a current diagnosis of mental health condition in coroner/medical examiner or law enforcement reports.

<sup>§</sup> OR reflects the risk among those without known mental health condition relative to those with known mental health condition.

<sup>¶</sup> Logistic regression was used to estimate adjusted OR with 95% CIs after controlling for age, sex, race, and ethnicity. Known mental health condition was the reference group.

\*\* Includes decedents with one or more diagnosed current mental health conditions, which are not mutually exclusive. Therefore, sums of percentages for the diagnosed conditions exceed 100%. Denominator includes the number of decedents with one or more current diagnosed mental health conditions.

<sup>††</sup> Not a diagnosis.

<sup>§§</sup> Denominator is decedents aged  $\geq 18$  years.

<sup>¶¶</sup> Denominator is decedents aged 10–18 years.

\*\*\* Denominator of institution subgroup is decedents with recent release from an institution. Recent release from an institution is defined as having occurred within the past month.

<sup>†††</sup> Denominator of crisis subgroup is decedents with any crisis within past or upcoming 2 weeks. Crises depicted here represent the most commonly occurring categories.

of affordable and effective treatment modalities, such as doctor-patient collaborative care models and proven cognitive-behavioral therapies. In addition, increased access to behavioral health providers in underserved areas is needed, as is expansion of health care systems that integrate physical and behavioral health, with a priority on suicide prevention and patient safety, especially through care transitions (12).

Comprehensive statewide suicide prevention activities are needed to address the full range of factors contributing to suicide. Prevention strategies include strengthening economic supports (e.g., housing stabilization policies, household financial support); teaching coping and problem-solving skills to manage everyday stressors and prevent future relationship problems, especially early in life; promoting social connectedness to increase a sense of belonging and access to informational, tangible, emotional, and social support; and identifying and better supporting persons at risk (e.g., military veterans, persons with physical/mental health conditions) (12). Other strategies include creating protective environments (e.g., reducing access to lethal means among persons at risk for suicide, creating organizational and workplace policies to promote help-seeking, easing transitions into and out of work for persons with mental health conditions and other life challenges), strengthening access and delivery of

care, supporting family and friends after a suicide, and assuring the media follow safe reporting recommendations (12). Some states, such as Colorado, are planning to implement such a comprehensive approach to suicide prevention (10).
